Abstract

Recent advances in measurements/observations have made it possible to test small and minute fundamental physical effects for transition rates and line strengths in many-electron atomic systems with unprecedented accuracies. This thesis provides high-precision calculations of line strengths and lifetimes for different atomic systems where we accurately account for various higher-order effects. In all these systems, systematically enlarged multiconfiguration Dirac-Hartree-Fock (MCDHF) wave functions are employed for calculation of the atomic states involved in the transitions to account for the relativistic correlation corrections.

Firstly, the QED sensitive magnetic dipole ($M1$) line strengths between the fine-structure levels of the ground configurations in B-, F-, Al- and Cl-like ions are calculated for the four elements argon, iron, molybdenum and tungsten. For these transitions, in addition to relativistic correlation corrections, the QED corrections are evaluated to all orders in αZ utilizing an effective potential approach. As a result, our calculations have reached an accuracy of 10^{-4} for the $M1$ line strengths. These accurate theoretical predictions provide the prerequisite for a test of QED by lifetime measurements at different frequencies and timescales. This will help to find a reason for the present discrepancies between theory and experiment for B-like Ar and Al-like Fe.

Secondly, the line strength of the $1s^2 2s 2p \ ^1P_1 - 1s^2 2s^2 \ ^1S_0$ spin allowed $E1$ transition in Be-like carbon is calculated. For this highly correlated transition, different correlation models are developed to account for all major electron-electron correlation contributions. The finite nuclear mass effect is accurately calculated taking into account the energy, wave functions as well as operator contributions. As a result, a reliable theoretical benchmark of $E1$ line strength with a relative accuracy of 1.5×10^{-4} is provided to support high precision lifetime measurement at GSI Darmstadt for the $1s^2 2s 2p \ ^1P_1$ state in Be-like carbon.

Finally, large-scale calculations are performed for all allowed ($E1$) and forbidden ($M1, E2, M2$) transitions among the fine structure levels of the $3s^2 3p^5$, $3s 3p^6$ and $3s^2 3p^4 3d$ configurations for Ni XII. Here, we validate all recently identified tentative experimental lines with one exception. Moreover, we present *ab initio* lifetimes that are better than previously reported *ab initio* and semi-empirical values as compared to available experimental data. Thus, we provide reliable predictions in the prospects of future experiments.

Zusammenfassung

Jüngste Fortschritte bei Messungen/Beobachtungen ermöglichen es, kleine und sehr kleine physikalische Effekte auf Übergangsraten und Linienstärken atomarer Mehrelektronensysteme mit nie dagewesener Genauigkeit zu testen. Diese Dissertation beinhaltet hochpräzise Berechnungen von Linienstärken und Lebensdauern für verschiedene atomare Systeme unter akkurater Berücksichtigung verschiedener Effekte höherer Ordnung. Bei allen diesen Systemen werden systematisch vergrößerte Multikonfigurations-Dirac-Hartree-Fock-Wellenfunktionen (MCDHF-Wellenfunktionen) verwendet, um relativistische Korrelationskorrekturen in die Berechnung der an den Übergängen beteiligten atomaren Zustände miteinzubeziehen.

Zuerst werden die QED-empfindlichen Linienstärken der magnetischen Dipolübergänge ($M1$ -Übergänge) zwischen den Feinstrukturniveaus der Grundkonfigurationen von B-, F-, Al- und Cl-ähnlichen Ionen der vier Elemente Argon, Eisen, Molybdän und Wolfram berechnet. Zusätzlich zu relativistischen Korrelationskorrekturen werden für diese Übergänge die QED-Korrekturen mittels eines effektiven Potentials in allen Ordnungen in αZ ausgewertet. Daraus resultiert eine Genauigkeit von 10^{-4} für die von uns berechneten $M1$ -Linienstärken. Diese akkuraten theoretischen Vorhersagen stellen die Voraussetzung für einen Test der QED durch Messungen von Lebensdauern bei verschiedenen Frequenzen und auf verschiedenen Zeitskalen dar. Dies wird dazu beitragen, einen Grund für die gegenwärtigen Diskrepanzen zwischen Theorie und Experiment im Bezug auf B-ähnliches Ar und Al-ähnliches Fe zu finden.

Zweitens wird die Linienstärke des spin-erlaubten $1s^2 2s 2p \ ^1P_1 - 1s^2 2s^2 \ ^1S_0$ $E1$ -Übergangs in Be-ähnlichem Kohlenstoff berechnet. Für diesen hochkorrelierten Übergang werden verschiedene Korrelationsmodelle entwickelt um die Beiträge aller wichtigen Elektron-Elektron-Korrelationen zu berücksichtigen. Der Effekt der endlichen Kernmasse wird präzise berechnet, unter Einbeziehung der Beiträge zu Energien, Wellenfunktionen und Operatoren. Daraus resultiert ein verlässlicher theoretischer Maßstab für die $E1$ -Linienstärke mit einer relativen Genauigkeit von 1.5×10^{-4} zur Unterstützung hochgenauer Messungen der Lebensdauer des $1s^2 2s 2p \ ^1P_1$ -Zustands in Be-ähnlichem Kohlenstoff an der GSI Darmstadt.

Zuletzt werden umfangreiche Berechnungen für alle erlaubten ($E1$) und verbotenen ($M1$, $E2$, $M2$) Übergänge zwischen den Feinstrukturniveaus der $3s^2 3p^5$ -, $3s 3p^6$ - und $3s^2 3p^4 3d$ -Konfigurationen in Ni XII durchgeführt. Hier bestätigen wir alle kürzlich identifizierten vorläufigen experimentellen Linien mit einer Ausnahme. Darüber hinaus präsentieren wir *Ab-initio*-Lebensdauern, die besser mit den verfügbaren experimentellen Daten übereinstimmen als bisherige *Ab-initio*- und semiempirische Werte, und stellen so verlässliche Vorhersagen für zukünftige Experimente bereit.

1 Introduction

Our understanding of the structure and dynamics of many-electron atoms and ions depends on a detailed analysis and comparison of theoretical predictions with experimental observations of atomic properties. Two important and complementary properties of atomic states are transition energies and transition rates. For transition energies, the present experimental accuracy reaches the order of $10^{-6} - 10^{-18}$ [1–3]. Here the interplay between experiment and theory has improved drastically our understanding of different (higher-order) effects, e.g., many-body relativistic, the Breit interaction, finite nuclear mass, and quantum electrodynamics (QED) effects [4, 5]. Moreover, this interplay has a great potential in the search for new physics [6] and it eventually leads towards testing the Standard Model. For example, QED has been tested at the level of 7.2% for the magnetic dipole ($M1$) transition energy between fine-structure levels of the ground configuration in B-like Ar [7–10].

It is equally desirable to test the Standard Model by high precision atomic lifetime (the inverse of the sum of all transition rates of a given atomic state) measurements [11]. For the transition rates and line strengths, in contrast, the accuracy level is often not yet sufficient to test QED, many-body relativistic effects, etc. This is partially due to theory and partially due to experiment. From theory: we know that transition rates depend on a higher power of transition energy and non-diagonal matrix elements i.e., line strengths of the multi-polar electromagnetic operators. In contrast to the calculation of transition energies, there is no variational principle available that defines a minimum condition for the optimization of non-diagonal matrix elements. For this reason, the many-body relativistic effects (and/or higher-order effects) are more difficult to capture. From experiments: most if not all the measurements/observations provide uncertainties in the region of 30 – 1% mainly due to systematic and statistical errors [11, 12].

For $M1$ transitions, however, there are two remarkable exceptions where accuracy in the order of 0.1% is claimed by efficiently controlling the systematic and statistical errors. These lifetime measurements were performed at the Heidelberg electron beam ion trap (HD-EBIT). The measured lifetime is reported as 9.573(4)(5)(stat/syst) ms for the $2s^22p\ ^2P_{3/2}$ level in B-like Ar [13] and 16.726(+20/-10) ms for the $3s^23p\ ^2P_{3/2}$ level in Al-like Fe [14]. These levels decay via an $M1$

transition to the ground states $2s^22p\ ^2P_{1/2}$ and $3s^23p\ ^2P_{1/2}$, respectively.

The line strengths for these $M1$ transitions, in the non-relativistic limit, are insensitive to the description of the many-electron wave functions. In other words, (almost) all correlation corrections are of relativistic origin and, therefore, suppressed by a factor αZ , where Z is the nuclear charge. These line strengths are especially sensitive to QED contributions. For instance, the leading QED effect of an order α , so-called electron anomalous magnetic moment (EAMM) correction, contributes to 0.46% [15]. Therefore, such $M1$ transition line strengths can be calculated very precisely and may be used as a benchmark for comparison with the experiment. However, the most precise theoretical evaluations for these line strengths in B-like ions [15–20] and in Al-like ions [21, 22] predict shorter lifetimes than measured experimentally [13, 14]. In fact, the deviation between theory and experiment is of the order of the EAMM, which led to speculation about the correctness of the inclusion of the EAMM into the transition amplitude. Let us note here that such high-precision measurements are available only from the HD-EBIT in the millisecond range. In the future, however, precise experiments for various lifetime and transition energy domains and by different techniques will hopefully solve the present discrepancy. Therefore, there is a strong need for a theoretical analysis of these systems where relativistic correlations and the QED contributions can be quantified as a benchmark principal for these experiments.

For the $E1$ strong transition, high hopes are pinned on the femtosecond laser technology [23], which has already demonstrated great success in studies of chemical reactions, wave function dynamics, photoionization time delays, etc. This technology allows to perform the highly accurate pump-probe atomic lifetime measurements. The pump-probe technique has been used already in the lifetime measurements of the $6P_{3/2}$ excited-state in cesium atom which is relevant to the atomic parity non-conservation [24, 25]. In contrast to neutral atoms, transitions to excited states in ions quickly reach the XUV- or X-ray energy range and, therefore, a high-photon flux of XUV- or X-ray source is required for pumping and/or probing processes. For instance, the Linac Coherent Light Source has been employed in the measurement of lifetimes in Ne-like iron [26]. Recently, it has been proposed to use a compact high-power XUV-ray source in a combination with the storage ring at GSI to perform precision spectroscopy and lifetime measurements of ions [27]. For this purpose, a novel high-photon flux XUV-radiation source based on the high harmonic

generation in argon has been developed, which provides ~ 100 femtosecond pulses at photon energies up to 26.6 eV [28, 29]. As the first experiment, the measurement of the lifetime of the $1s^2 2s 2p \ ^1P_1$ state in Be-like carbon is proposed with a relative accuracy in the order of $10^{-4} - 10^{-5}$ [27].

The excited state $1s^2 2s 2p \ ^1P_1$ decays to the $1s^2 2s^2 \ ^1S_0$ ground state through a strong spin allowed $E1$ transition. For the line strength of this transition, theoretical testing of higher-order physics is a formidable task. Be-like carbon is low charge state ion and this transition is within the same shell ($\Delta n = 0$). Here the biggest challenge is to control uncertainties due to electron-electron correlations. During past years, various theoretical studies have been reported for this line strength [30–36]. As a result, the most accurate theoretical calculations [32, 35, 36] report an accuracy in the order of 10^{-3} . Since the expected experimental accuracy is much better, there is a need for further improvements in the theoretical calculations.

The other important realm of the interplay between theory and observation is diagnostic of astrophysical and laboratory plasmas. The astrophysical and plasma physics communities require new and increasingly accurate theoretical predictions for the identification and interpretation of the high-resolution spectroscopic observations of ionized atoms in all ionization stages. In addition to the quality, the quantity of spectra of these stripped ions is also needed for the determination of plasma parameters, such as electron temperature, electron density, elemental abundances, etc [37].

Chlorine like nickel (Ni XII) is an important member in the group of iron-peak elements. Such nickel ions exist in different astronomical objects [38–42]. Indeed, nickel has been found the second most abundant transition element in our sun after iron. Extreme ultraviolet (EUV) and soft x-rays from Ni XII are prominent in solar emission lines and also in solar-type stars [43–45]. Moreover, Edlen and Smitt have observed several forbidden coronal lines in the visible and UV region of the solar spectrum from such ions [46]. Similarly, nickel is also an important impurity element in the Joint European Torus (JET) (from both divertor and limiter configurations) [47] as well as in many other tokamak fusion test reactor plasmas [48–50]. Several EUV emission lines from Ni XII have also been observed in beam-foil experiment in laboratory plasma [51, 52].

Despite the importance of Ni XII ions, only a few of the level energies are well characterized in the literature [53]. This is mainly because the experimental data

can only be compared with less predictive *ab initio* or even semi-empirical calculations. Very recently, Del Zanna and Badnell suggested several new experimental excitation energies for Ni XII based on different observations [54] and semi-empirical term energy correction method [55, 56]. They then used their semi-empirical data combined with experimental data for the determination of the transition rates and electron impact excitation rates for Ni XII [54]. The semi-empirical formalism is often advantageous, this, however may contain a source of ambiguity because these predictions are not fully according to atomic structure theory [11, 57]. The reliability of this formalism can be improved by either more experimental data are available in advance for the theoretical adjustments or by the comparison with accurate *ab initio* calculations.

In this thesis, we focus on three regimes of high-precision calculations for transition rates in many-electron atomic systems in the view of continuous experimental/observational advances as mentioned above. The thesis is structured in the following way:

We start with Chapter 2 where we explain the generation of approximate relativistic wave functions for many-electron atomic systems within the framework of the multi-configuration Dirac-Hartree-Fock method (MCDHF) method. These approximate wave functions are improved by systematically enlarging the configuration space to include the correlation effects. Further improvements are implemented by including Breit, first order QED and finite nuclear mass corrections. Then these wave functions are used to calculate the transition amplitudes necessary for the calculation of transition properties of different multi-pole expansions of the electromagnetic field.

In Chapter 3, we present a detailed study for the line strengths of QED-sensitive $M1$ forbidden transitions between the fine-structure levels of the ground configurations in B-, Al-, F- and Cl-like ions. The ground configurations of B-like and Al-like ions have a valence p -electron in the L shell and M shell, respectively. These configurations are also quite similar to the ground configurations of F-like and Cl-like ions but with a p -shell vacancy in the L shell and M shell, respectively. The major difference between the two systems of ions is the flip of fine-structure levels where the excited 2P levels dominantly decay through $M1$ transition to the ground-state 2P levels. We predict lifetimes in the millisecond to picoseconds range with a relative accuracy of 10^{-4} by means of our accurate line strengths

Chapter 4 deals with a detailed calculation of $E1$ line strength of the $1s^2 2s 2p\ ^1P_1 - 1s^2 2s^2\ ^1S_0$ transition in Be-like carbon. Contrary to $M1$ transition, this transition is highly correlated. Here, we develop various electron correlation models and use orthogonal and nonorthogonal set of orbitals for the initial and final states in these correlation models. We find that the accuracy assessment, based on an agreement between the gauges, might lead to a significant error underestimation. For this reason, we estimate the uncertainty from the differences between the results obtained within all the correlation models developed. Finally, we analyse the effect of the finite nuclear mass to the line strength and demonstrate its gauge invariance as we take the recoil correction to the transition operator into account. We obtain a calculated line strength of 2.43926(37) with a relative accuracy of 1.5×10^{-4} .

In Chapter 5, we perform intensive computation to improve the database for transition rates, oscillator strengths, and lifetimes on Ni XII, an important astrophysical ion. Thereby, we take into account all allowed $E1$ and forbidden $M1$, $E2$, and $M2$ transitions among the first 31 lowest energy levels. These lines arise from three configurations $3s^2 3p^5$, $3s 3p^6$ and $3s^2 3p^4 3d$. We present the same level of accuracy or even better than the semi-empirical calculations. We testify recent tentative identification for the observed lines, and then predict the atomic data for the lines which have not been observed yet.

Finally, the results of this thesis are summarized in Chapter 6.

The atomic units ($\hbar = 1$, $e = 1$, $m_e = 1$, $c = 1/\alpha$) are used throughout the work unless stated otherwise.

2 Many-electron wave functions

The laws of nature should be expressed in beautiful equations.

Paul M. Dirac (1902 – 1984)

2.1 Dirac-Coulomb Hamiltonian

Like in one electron systems, the first step for the calculations of atomic stationary states and transitions among them for atoms or ions with N electrons is writing down the Hamiltonian \hat{H} to be used in solving the wave equation (eigenvalue problem)

$$\hat{H}\Psi = E\Psi. \quad (2.1)$$

for the complete atomic wave function Ψ [58]. Here the Hamiltonian \hat{H} is the sum of N one-electron contributions $\hat{H}(i)$ and $N(N-1)/2$ two-electron contributions $\hat{H}(ij)$ so that

$$\hat{H} = \sum_{i=1}^N \hat{H}(i) + \sum_{i<j}^N \hat{H}(ij). \quad (2.2)$$

For the relativistic calculations of the atomic stationary states, the dominant relativistic corrections are considered by accounting for the motion of each electron according to Dirac theory for the one-electron operator and by considering only the instantaneous Coulomb interaction for the two-electron operator [59, 60]. The resulting Hamiltonian is the so-called Dirac-Coulomb Hamiltonian given as

$$\begin{aligned} \hat{H}_{\text{DC}} &= \sum_{i=1}^N \hat{h}_{\text{D}}(i) + \sum_{i<j}^N \frac{1}{r_{ij}} \\ &= \sum_{i=1}^N \left[c\boldsymbol{\alpha}_i \cdot \mathbf{p}_i + (\beta_i - 1)c^2 + V_{\text{nuc}}(r_i) \right] + \sum_{i<j}^N \frac{1}{r_{ij}}, \end{aligned} \quad (2.3)$$

where \hat{h}_{D} is the one electron Dirac Hamiltonian, c is the speed of light, $V_{\text{nuc}}(r_i)$ is usually considered as an effective electron-nucleus potential at radius r_i by taking into account the finite size of the nuclear charge distribution through a two parameter Fermi distribution of the charge, $\mathbf{p} \equiv -i\nabla$ the electron momentum operator and

$r_{ij} = |\mathbf{r}_i - \mathbf{r}_j|$ is the distance between electrons i and j . The $\boldsymbol{\alpha}$ and β are 4×4 Dirac matrices given by

$$\alpha_i = \begin{pmatrix} 0 & \sigma_i \\ \sigma_i & 0 \end{pmatrix}, \quad \beta = \begin{pmatrix} I & 0 \\ 0 & -I \end{pmatrix}. \quad (2.4)$$

in terms of the 2×2 Pauli matrices σ_i and zero and unit matrix I . Explicitly, in \hat{H}_{DC} (2.3) the one electron terms describe the kinetic and potential energy of the each electron with respect to nucleus, and the two electron terms the Coulomb potential energy between any two electrons.

2.2 Central field approximations

The two electrons terms in the Hamiltonian (2.3) are problematic in that they destroy the separability of the Hamiltonian and introduce singularities into the wave equation when $r_{ij} = 0$. These electron-electron interactions make the exact solution of the Eq. (2.1) almost impossible. One possibility to get the insight into the nature of the wave function is to apply such physical approximations to the Hamiltonian (2.3) so that the Eq. (2.1) is solvable. One such approximation is central-field approximation which has proved quite successful. According to this approximation \hat{H}_{DC} can be written as

$$\hat{H}_o = \sum_{i=1}^N \left[c\boldsymbol{\alpha}_i \cdot \mathbf{p}_i + (\beta_i - 1)c^2 + V_{\text{nuc}}(r_i) + u_i(r_i) \right], \quad (2.5)$$

where $u_i(r_i)$ depends only on r and not on the angular coordinates. In this approximation each electron is assumed to move in a spherically symmetric, electrostatic potential which is independent of the other electrons but is the time-averaged field of the $N - 1$ electrons. We can define a central field as $V_i^C(r) = V_{\text{nuc}}(r) + u_i(r)$ of spherical symmetry for each electron. This leads to the so-called independent particle model where many-electron wave functions can be expressed as a simple product of one electron solutions of the Eq. (2.5).

The approximate Hamiltonian \hat{H}_o commutes with \hat{H}_{DC} as well as with total angular momentum operators \mathbf{J}^2 and J_z . We may choose the eigenfunction of \hat{H}_o

which are also eigenfunctions of these operators. Similar to Eq. (2.1) we can write,

$$\hat{H}_o \Psi_o = E_o \Psi_o. \quad (2.6)$$

As mentioned above, \hat{H}_o is separable we can write,

$$E_o = \sum_{i=1}^N E_i, \quad (2.7)$$

and

$$\Psi_o = \prod_{i=1}^N \phi_{a_i}(\mathbf{r}_i). \quad (2.8)$$

where a represents all of the quantum numbers and $\phi_{a_i}(\mathbf{r})$ are Dirac orbitals which are the solution of the Dirac equation

$$\left[c\boldsymbol{\alpha} \cdot \mathbf{p} + (\beta - 1)c^2 + V^C(r) \right] \phi(a; \mathbf{r}) = E \phi_a(\mathbf{r}). \quad (2.9)$$

The individual Dirac orbital has the following four-spinor form in a spherical coordinate system of (r, θ, φ) ,

$$\phi_{n\kappa m}(\mathbf{r}) = \frac{1}{r} \begin{pmatrix} P_{n\kappa}(r) \chi_{\kappa m}(\theta, \varphi) \\ iQ_{n\kappa}(r) \chi_{-\kappa m}(\theta, \varphi) \end{pmatrix}, \quad \text{with} \quad \langle \phi_a | \phi_b \rangle = \delta_{ab}. \quad (2.10)$$

In this four-spinor expression, n is the principal quantum number of bound electrons, κ is the relativistic quantum number, which has $\kappa = \pm(j + \frac{1}{2})$ for $j = l \mp \frac{1}{2}$, and m is the projection of the total angular momentum j on the quantization axis. In the expression (2.10), $P_{n\kappa}(r)$ and $Q_{n\kappa}(r)$ denote the large and small components of the electron radial wave functions. The two-component function $\chi_{\kappa m}(\theta, \varphi)$ is referred to as the spin-angular function and is defined by [61],

$$\chi_{\kappa m}(\theta, \varphi) = \sum_{m_s=\pm 1/2} \langle l, m - m_s; 1/2, m_s | jm \rangle Y_{l, m-m_s}(\theta, \varphi) \xi_{m_s}, \quad (2.11)$$

where $\langle l, m - m_s; 1/2, m_s | jm \rangle$ denotes a Clebsch-Gordan coefficient, $Y_{l, m-m_s}(\theta, \varphi)$ is a spherical harmonic, and

$$\xi_{+1/2} = \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \quad \xi_{-1/2} = \begin{pmatrix} 0 \\ 1 \end{pmatrix}. \quad (2.12)$$

2.3 Configuration state function

In the non-relativistic case, one approach to obtain the approximate wave function (2.8) is Hartree approximation. This approximation, however, does not give the antisymmetric wave function since the electrons are indistinguishable fermions and Pauli exclusion principle is not satisfied. Pauli exclusion principle can be satisfied by taking an approximate wave function in the form of a Slater determinant:

$$\Psi_o = \frac{1}{\sqrt{N!}} \begin{vmatrix} \phi_{a_1}(\mathbf{r}_1) & \phi_{a_1}(\mathbf{r}_2) & \cdots & \phi_{a_1}(\mathbf{r}_N) \\ \phi_{a_2}(\mathbf{r}_1) & \phi_{a_2}(\mathbf{r}_2) & \cdots & \phi_{a_2}(\mathbf{r}_N) \\ \vdots & \vdots & \ddots & \vdots \\ \phi_{a_N}(\mathbf{r}_1) & \phi_{a_N}(\mathbf{r}_2) & \cdots & \phi_{a_N}(\mathbf{r}_N) \end{vmatrix}. \quad (2.13)$$

Here, $N!$ is the factorial of N . The approximate wave functions in the form of Slater determinant, however, are not eigenfunctions of total angular momentum operator. Since the aim is to construct the basis functions which give the approximate wave functions as close as possible to accurate wave functions; the basis are taken in the form of configuration state functions (CSFs).

A CSF, represented as $\Phi(\gamma; \pi JM)$, is formed by taking linear combination of Slater determinants (2.13) constructed from the orbitals (2.10) so as to obtain normalized ($\langle \Phi(\gamma; \pi JM) | \Phi(\gamma; \pi JM) \rangle = 1$) eigenfunctions of the total angular momentum operators \mathbf{J}^2 and J_z , and parity π . The label γ represents the electron configuration and all information such as orbital occupation numbers, coupling, seniority numbers, etc., required to define the CSF uniquely. The Slater determinants in a CSF belong to same electronic configuration, i.e. with same n and l quantum numbers but with different m quantum numbers. This process is known as coupling and the CSFs are also referred coupled basis functions.

In our discussion so far, we have shown how the exact wave function can be approximated as a single CSF ($\Psi = \Phi(\gamma; \pi JM)$) which is constructed by taking the radial wave functions of the approximations (2.5) and angular coupling between the orbitals. Now we want to improve the accuracy of the approximate wave function by determining the set of radial wave functions that will provide the best estimate. One such way is to apply the variational method to optimize the total energy so that the energy functional is stationary with respect to variation in the radial wave functions which leads to so-called Dirac-Hartree-Fock (DHF) equations. This approximation

is called DHF approximation and the approximate wave functions are called DHF wave functions. The derivations and solution method of these equations can be considered as a special case of the approximations that we will discuss in the next section.

The DHF method predicts many atomic properties remarkably well, however, for the high precision calculations these are considered insufficient. As this is independent particle method, where the electrons are assumed to move in an average, central field of the other electrons and the nucleus, so the notion of ‘correlation in the motion of the electrons (electron-electron correlations)’ is entirely neglected.

2.4 Multi-configuration Dirac-Hartree-Fock method

To effectively evaluate the electron-electron correlation effects, here we use the multiconfiguration Dirac-Hartree-Fock (MCDHF) method in jj -coupling [59, 60]. In this method, the wave function Ψ of an atomic state label Γ , total angular momentum quantum number J , magnetic quantum number M and parity π is referred to as an atomic state function (ASF) which is represented as $\Psi(\Gamma; \pi JM)$. In contrast to DHF method, in MCDHF method the ASF is expanded in the basis of, say n_c CSFs of the same symmetry:

$$\Psi(\Gamma; \pi JM) = \sum_{j=1}^{n_c} C_j^\Gamma \Phi(\gamma_j; \pi JM), \quad \text{where} \quad \sum_{j=1}^{n_c} |C_j^\Gamma|^2 = 1. \quad (2.14)$$

Here C_j^Γ are the expansion coefficients or weights which represent the atomic state Γ in the basis of CSFs. The expansion coefficients may be combined in column vector $\mathbf{C}^\Gamma \equiv \{C_j^\Gamma, j = 1, \dots, n_c\}$. In single CSF case (DHF), only the radial functions are varied. However, in MCDHF approach there are two phases of optimization need to be performed simultaneously on the basis of Dirac-Coulomb Hamiltonian (2.3):

- the determination of C_j^Γ coefficients for a given set of CSFs. This process is called relativistic configuration interaction (RCI) process and
- optimization of the radial wave functions that define the orbitals for the construction of basis of CSFs for a given set of C_j^Γ coefficients.

Now we explain in some details about the variational formalism for the optimization processes mentioned above. Basically, the variational method for solving

the Eq. (2.1) relies on the reformulation of the eigenvalue problem. For the normalized wave function $\Psi(\Gamma; \pi JM)$ the total energy is the expectation value of the Hamiltonian \hat{H}_{DC} (2.3), referred to as energy functional,

$$E[\Psi] = \langle \Psi | \hat{H}_{\text{DC}} | \Psi \rangle, \quad \text{with the condition} \quad \langle \Psi | \Psi \rangle = 1. \quad (2.15)$$

It is obvious that the definition of $\Psi(\Gamma; \pi JM_J)$ includes the radial functions and expansion coefficients. These are varied to get the best estimate Ψ^{best} which leaves the energy functional stationary ($\delta E = 0$) with respect to variations $\delta \Psi$ so that $\delta \Psi$ is orthogonal to Ψ with the boundary conditions, namely

$$\langle \delta \Psi | \hat{H}_{\text{DC}} - E | \Psi^{\text{best}} \rangle = 0. \quad (2.16)$$

The orthogonality constraints must also be included in the variational process. As a result, the allowed variations of the radial functions are of two types: those that involve only a single radial function and those that require that two radial functions be perturbed simultaneously in order to maintain orthonormality.

We explain in some more details about the derivations and solution method for the MCDHF equations. Let a, b, c, \dots represent one-electron radial functions for an orthonormal set of Dirac orbitals (2.10) with associated quantum numbers $n_a \kappa_a, n_b \kappa_b, n_c \kappa_c, \dots$. The resulting energy functional is written in the form

$$\mathcal{F}(\{c\}, \{P\}, \{Q\}; \gamma J) = \langle \Psi | \hat{H}_{\text{DC}} | \Psi \rangle + \sum_{ab} \delta_{\kappa_a \kappa_b} \lambda_{ab} \mathcal{C}_{ab}. \quad (2.17)$$

In this expression, the Lagrange multipliers λ_{ab} for orbitals a and b belonging to same κ space ($\kappa_a = \kappa_b$) are introduced to constrain the variations in the one-electron functions ($\delta P_{n\kappa}, \delta Q_{n\kappa}$), namely

$$\mathcal{C}_{ab} \equiv \int [P_a(r)P_b(r) + Q_a(r)Q_b(r)] dr - \delta_{n_a n_b} = 0. \quad (2.18)$$

which guarantees the orthonormality of the one-electron functions as well as of the CSFs.

The energy (2.15) associated to an ASF (Γ) can be represented in the matrix

form as,

$$\begin{aligned}
E_{\text{DC}}^{(\Gamma;\pi JM)} &= \langle \Psi(\Gamma; \pi JM) | \hat{H}_{\text{DC}} | \Psi(\Gamma; \pi JM) \rangle \\
&= \sum_{i,j} C_i^{\Gamma*} C_j^{\Gamma} \langle \Phi(\gamma_i; \pi J) | \hat{H}_{\text{DC}} | \Phi(\gamma_j; \pi J) \rangle \\
&= \sum_{i,j} C_i^{\Gamma*} C_j^{\Gamma} H_{ij}^{(\Gamma;\pi J)}.
\end{aligned} \tag{2.19}$$

where $\mathbf{H}^{(\Gamma;\pi J)}$ is matrix of dimension $n_c \times n_c$ with elements $H_{ij}^{(\Gamma;\pi J)}$. The Hamiltonian \hat{H}_{DC} is invariant under spatial rotation and reflections therefore the elements $H_{ij}^{(\Gamma;\pi J)}$ are independent of the projection quantum number M . We can skip projection quantum number M in the definition of CSF for the energy expression. The predicted atomic energy levels $E^{(\Gamma;\pi JM)}$ can be taken to be the eigenvalues of $\mathbf{H}^{(\Gamma;\pi J)}$ and C_i^{Γ} are components of associated eigenvectors. Therefore, the construction of the matrix $\mathbf{H}^{(\Gamma;\pi J)}$ with respect to the basis of CSFs plays a central role in RCI and MCDHF calculations.

Traditionally, the matrix $\mathbf{H}^{(\Gamma;\pi J)}$ among the basis of CSFs can be expressed in terms of spin angular coefficients and radial integrals

$$\langle \Psi | \hat{H}_{\text{DC}} | \Psi \rangle = \sum_{ab} t_{ab} I(a, b) + \sum_{abcd;k} v_{abcd}^k R^k(ab, cd). \tag{2.20}$$

In this expansion,

$$t_{ab} = \sum_{ij} t_{ab}^{ij} C_i^{\Gamma} C_j^{\Gamma}, \quad v_{abcd;k} = \sum_{ij} v_{abcd;k}^{ij} C_i^{\Gamma} C_j^{\Gamma}, \tag{2.21}$$

are the angular coefficients (scalar) which arise from integrating over the angular degrees of freedom and depend on the angular coupling scheme of the CSFs i and j and on orbital angular momenta j_a, j_b, j_c, j_d . The expressions $I(a, b)$ and $R^k(ab, cd)$ are one-electron and two-electron relativistic integrals over radial amplitudes, re-

spectively, given as

$$\begin{aligned}
I(a, b) &= \langle a | h_D | b \rangle \\
&= \delta_{\kappa_a \kappa_b} \int_0^\infty \{ P_a(r) V_{\text{nuc}}(r) P_b(r) \\
&\quad - c P_a(r) \left(\frac{d}{dr} - \frac{\kappa_a}{r} \right) Q_b(r) \\
&\quad + c Q_a(r) \left(\frac{d}{dr} + \frac{\kappa_a}{r} \right) P_b(r) \\
&\quad + Q_a(r) (V_{\text{nuc}}(r) - 2c^2) Q_b(r) \} dr, \tag{2.22}
\end{aligned}$$

which contains the kinetic and potential energy of an electron in a subshell, and

$$R^k(ab, cd) = \int_0^\infty [P_{n_a \kappa_a}(r) P_{n_c \kappa_c}(r) + Q_{n_a \kappa_a}(r) Q_{n_c \kappa_c}(r)] \frac{1}{r} Y^k(bd; r) dr, \tag{2.23}$$

describe the effective interaction strength of the four electrons involved in the interaction [62]. In this expression the Y^k functions are defined as

$$Y^k(ab; r) = r \int_0^\infty \frac{r_{<}^k}{r_{>}^{k+1}} [P_{n_a \kappa_a}(s) P_{n_b \kappa_b}(s) + Q_{n_a \kappa_a}(s) Q_{n_b \kappa_b}(s)] ds. \tag{2.24}$$

Here $r_{>}$ ($r_{<}$) denotes the greater (lesser) of r and s .

In RCI problem, the CSFs are assumed to be known by taking some initial estimate of the radial functions $\{P_{n\kappa}, Q_{n\kappa}\}$ and only the expansion coefficients $\mathbf{C}^\Gamma \equiv \{C_j^\Gamma, j = 1, \dots, n_c\}$ are optimized by demanding that the functional (2.17) be stationary with respect to variation in coefficients leading to eigenvalue problem for the expansion coefficients,

$$(\mathbf{H}^{(\Gamma; \pi J)} - E_{\text{DC}}^{(\Gamma; \pi J)} \mathbf{1}) \mathbf{C}^\Gamma = 0. \tag{2.25}$$

Here $\mathbf{1}$ is $n_c \times n_c$ unit matrix. This equations has many solutions. Only one eigenvector is desired eigenvector, not necessarily the lowest one, and this vector defines the expansion coefficients.

Finally, for a given set of expansion coefficients \mathbf{C}^Γ , the stationary condition with respect to the variations in both large and small component of the radial

functions result in coupled MCDHF equations:

$$w_a \begin{bmatrix} V(a; r) & -c \left[\frac{d}{dr} - \frac{\kappa_a}{r} \right] \\ c \left[\frac{d}{dr} - \frac{\kappa_a}{r} \right] & V(a; r) - 2c^2 \end{bmatrix} \begin{bmatrix} P_a(r) \\ Q_a(r) \end{bmatrix} = \sum_b \varepsilon_{ab} \delta_{\kappa_a \kappa_b} \begin{bmatrix} P_a(r) \\ Q_a(r) \end{bmatrix}, \quad (2.26)$$

where $V(a; r) = (V_{\text{nuc}}(r) + Y(a; r) + \bar{X}(a; r))$. In this expression $Y(a; r)$ is direct potential and $\bar{X}(a; r)$ contains the exchange contributions arising from both diagonal and off-diagonal matrix elements appearing in expression (2.19). In each κ -space, Lagrange related energy parameters ε_{ab} are introduced to impose the orthonormality constraint (2.18) in the variational process.

Taking an initial estimate of the radial functions, solutions to MCDHF equations are obtained by an iterative process which is referred to as self-consistent field (SCF) method. Very efficient methods are used to solve the differential equations by using finite difference methods where the radial functions are represented on a logarithmic mesh. Essentially, in every iteration, the method improves the radial functions.

As explained earlier, the equations for the expansion coefficients and the radial functions are coupled, the RCI problem and the SCF process are iterated until the radial orbitals and the energies are converged to a specific tolerance.

For the construction of the variational functional, we have a choice of combining expressions for the energies of one or more ASFs. Moreover, ASFs can be included in the calculations to have different total angular momenta. If the functionals are weighted sums of energies of all possible ASFs that may be constructed from a given set of CSFs then these are called average level (AL) calculations. In this case, the number of ASFs is same as the number, n_c , of CSFs in the set. If the configuration included in the calculation have differing total angular momenta, then the extension of the AL method is called extended average level (EAL) [63].

If a variational functional is constructed to minimize the energy for only one ASF then this scheme is called the optimal level (OL) scheme. Whereas in the extended optimal level (EOL) scheme the calculations can be extended to include several ASFs. In this case the ASFs which are subset of the total ASFs that can be generated from a given set of configurations. In EOL case, the energy functional contains the weights only for the levels under consideration [63]. In this thesis, we have employed OL and EOL schemes for the optimization of atomic states. This

gives us freedom to choose simultaneous or separate optimization of the orbitals for the desired ASFs. We will explain the details of atomic systems and relevant atomic states in the later Chapters.

For the implementation of MCDHF/RCI methods, the credit goes to two main developments in the form of computer programs [61, 63]. However, the application and scope of the problem were limited due to available computer resources and numerical algorithms to solve the equations. Almost a decade later from these developments, there was a tremendous improvement in this regard in the form of *General-purpose Relativistic Atomic Structure Program* (GRASP)[64] which is an assembly of different codes. And then there were many modifications and extensions to the GRASP to increase the accuracy of the atomic properties by improving the computational capabilities to increase the size of the wave functions [65–67]. The widely used latest versions are GRASP2K [68] and its descendant in Fortran 95 with name GRASP2018 [69]. In the work presented in this thesis, we have employed the latest version GRASP2K [68] to generate energy levels and wave functions of atomic states of many-electron atoms and ions for the calculations of necessary transition properties.

The latest version GRASP2K can generate the wave functions comprising of millions of CSFs. However, it is not possible to optimize all radial orbitals belonging to these wave functions simultaneously. Instead, the calculations are done layer by layer in a procedure of active set approach. We explain this procedure in the next section.

2.5 Active set approach

For many atomic properties, if the electron-electron interactions are considered in full extent even for a small number of electrons (say, $N = 4$), the computations become a formidable task. The basis sets are infinite, but in practice, the basis set must be restricted to a finite subset making the choice of basis and subset an important factor that most of the time depends on the property and the system under study. Some systems are highly correlated (e.g., near neutral atomic systems particularly for $E1$ transitions) and other are less correlated (e.g. $M1$ transitions between the fine structure states belonging to the same configuration). We shall describe this correlation business in detail for different systems and related correlations effects in

the later Chapters.

Briefly, in all those atomic systems we have incorporated important electron correlations using systematically enlarged many-electron wave functions i.e., the configuration space is systematically extended using the active set approach and monitoring the numerical convergence of the desired parameters. In the active set approach, the electrons are virtually excited from reference configurations to a set of orbitals called the active set. The calculations are started for the lowest order of approximations where the orbitals belonging to the so-called reference configurations are optimized spectroscopically, i.e., the orbitals are required to have a node structure similar to corresponding hydrogenic orbitals. These orbitals are named as spectroscopic orbitals. After the initial calculations, the wave functions are systematically improved by performing MCDHF calculations for each new layer of orbitals and keeping the previously calculated orbitals fixed. These added orbitals are called correlation orbitals. For each new layer of correlation orbitals the basis of CSFs is expanded by including further single (S), single and double (SD), single, double and triple (SDT) and some times single, double, triple and quadruple (SDTQ) virtual excitations from the configurations defining the reference set to the active set of orbitals [67].

2.6 Higher-order corrections

For high precision calculations of the many-electrons systems, one needs to go beyond the instantaneous Coulomb interaction for the two-electron operator defined in Dirac-Coulomb Hamiltonian (2.3).

2.6.1 Breit correction

The leading corrections to instantaneous Coulomb interaction, such as magnetic interaction and the effects of retardation, are implemented using assumption based on one-electron concepts [70]. Taking the approximation of the order α^2 from QED, one can derive the so-called transverse photon interaction Hamiltonian which is

given as

$$\begin{aligned}\hat{H}_{\text{TP}} = & -\sum_{i<j}^N \left[\boldsymbol{\alpha}_i \cdot \boldsymbol{\alpha}_j \frac{\cos(\omega_{ij}r_{ij}/c)}{r_{ij}} \right. \\ & \left. + (\boldsymbol{\alpha}_i \cdot \boldsymbol{\nabla}_i)(\boldsymbol{\alpha}_j \cdot \boldsymbol{\nabla}_j) \frac{\cos(\omega_{ij}r_{ij}/c) - 1}{\omega_{ij}^2 r_{ij}/c^2} \right].\end{aligned}\quad (2.27)$$

In this expression, given in Coulomb gauge, ω_{ij} represents the energy of the virtual exchanged photon between two electrons introduced in QED, even in the absence of the emission or absorption of ‘real’ radiation. The value of ω_{ij} can be interpreted in terms of differences in orbital one-electron energies. This may be an appropriate assumption for singly occupied orbitals but is not correct for multiply occupied ones and certainly is not true for correlation orbitals. For these reasons transverse photon interaction is often computed in the low-frequency limit ($\omega_{ij} \rightarrow 0$), the expression (2.27) reduces to frequency independent Breit interaction (that most of the time is called the Breit interaction) given as

$$\hat{H}_{\text{Breit}} = -\sum_{i<j}^N \frac{1}{2r_{ij}} \left[\boldsymbol{\alpha}_i \cdot \boldsymbol{\alpha}_j + \frac{(\boldsymbol{\alpha}_i \cdot \mathbf{r}_{ij})(\boldsymbol{\alpha}_j \cdot \mathbf{r}_{ij})}{r_{ij}^2} \right]. \quad (2.28)$$

Adding (2.28) to the Dirac-Coulomb Hamiltonian (2.3) gives the Dirac-Coulomb-Breit Hamiltonian (in the effective Coulomb gauge)

$$\hat{H}_{\text{DCB}} = \hat{H}_{\text{DC}} + \hat{H}_{\text{Breit}}. \quad (2.29)$$

2.6.2 QED corrections

The leading quantum electrodynamic (QED) corrections; the self-energy (SE) correction and the vacuum polarization (VP) can be added to \hat{H}_{DCB} to yield the updated Hamiltonian

$$\hat{H}_{\text{DCB+QED}} = \hat{H}_{\text{DCB}} + \hat{H}_{\text{SE}} + \hat{H}_{\text{VP}}. \quad (2.30)$$

Here \hat{H}_{SE} provides the SE correction. This correction arises from the interaction of the electron with its own radiation field. This correction is applied to diagonal

energies as

$$\langle \Phi(\gamma_i; \pi J) | \hat{H}_{\text{SE}} | \Phi(\gamma_i; \pi J) \rangle = \sum_{a=1}^{n_w} w_a E_{\text{SE}(a)} , \quad (2.31)$$

where n_w is the number of subshells in the CSF, n_a is the number of electrons in subshell a in the CSF, $E_{\text{SE}(a)}$ is the one-electron self-energy of an electron in subshell a . In GRASP2K [68] the self-energy correction is computed from a screened-hydrogenic approximation, a model that does not apply well to correlation orbitals that are far from hydrogenic approximations. It is better to specify the largest principal quantum number for which CSFs are to be considered in the self-energy correction. For small calculations with a few correlation orbitals this cut-off is set to the largest principal quantum number of the included orbitals. In large calculations with many correlation orbitals the cut-off is typically set to a number which is just one/two number larger than the highest principal quantum number of the spectroscopic orbitals.

In the expression (2.30), \hat{H}_{VP} provides the correction due to vacuum polarization, which is related to the creation and annihilation of virtual electron-positron pairs in the field of the nucleus. This correction is applied to all matrix elements

$$\langle \Phi(\gamma_i; \pi J) | \hat{H}_{\text{VP}} | \Phi(\gamma_j; \pi J) \rangle = \langle \Phi(\gamma_i; \pi J) | \sum_i^N V_{\text{Uehl}}(r) | \Phi(\gamma_j; \pi J) \rangle , \quad (2.32)$$

where $V_{\text{Uehl}}(r)$ is Uehling potential which describe correction to the nuclear Coulomb potential. It includes vacuum polarization potential terms of both second- and fourth-order in QED perturbation theory [60].

2.6.3 Nuclear recoil correction

The correction due to the finite nuclear mass is much more difficult to consider. In non-relativistic theory, the center-of-mass motion can be separated off exactly. For one-electron ions, this simply leads to using a reduced mass for the electron, for many-electron atoms mass polarization terms arise which are the origin of the Hughes-Eckart shifts [71]. The full relativistic theory of the nuclear recoil effect can be formulated only within quantum electrodynamics [72]. However, the lowest order relativistic nuclear recoil correction can be applied to get the leading order nuclear recoil correction [73].

The lowest order nuclear motional corrections, namely the normal mass shift (NMS) term based on Dirac kinetic energy operator

$$\hat{H}_{\text{NMS}} = \frac{1}{M} \sum_{i=1}^N \left[c \boldsymbol{\alpha}_i \cdot \mathbf{p}_i + (\beta_i - 1) c^2 \right], \quad (2.33)$$

where M is the nuclear mass, and mass polarization term named as the specific mass shift (SMS)

$$\hat{H}_{\text{SMS}} = \frac{1}{M} \sum_{i < j=1}^N \mathbf{p}_i \cdot \mathbf{p}_j, \quad (2.34)$$

are added to the Dirac-Coulomb Hamiltonian (2.3).

Breit, QED and nuclear recoil corrections are computed using the MCDHF orbitals from a calculation using the Dirac-Coulomb Hamiltonian (2.3) and then applying only the RCI method with a Hamiltonian that includes the desired corrections. Generally, the most important correction is the Breit correction with the Dirac-Coulomb-Breit Hamiltonian (2.28) [60].

In the following section, we will briefly explain how the obtained wave functions are further utilized to calculate the many-electron transition properties.

2.7 Many-electron transition amplitudes

After each layer of MCDHF and subsequently RCI calculations, transition properties, such as transition rates A , line strengths S , and weighted oscillator strengths gf from atomic state Γ_i to atomic state Γ_j are computed in terms of reduced matrix elements:

$$\langle \Psi(\Gamma_i; \pi_i J_i) | \mathbf{T}^{\text{EMK}} | \Psi(\Gamma_j; \pi_j J_j) \rangle, \quad (2.35)$$

where the operator \mathbf{T}^{EMK} depends on the multipolarity, $E1, M1, E2, M2$, etc., of the transition. Inserting the CSF expansions for the atomic states, the reduced matrix element are expressed as sum over reduced matrix elements between CSFs

$$\begin{aligned} & \langle \Psi(\Gamma_i; \pi_i J_i) | \mathbf{T}^{\text{EMK}} | \Psi(\Gamma_j; \pi_j J_j) \rangle \\ &= \sum_{i,j} C_i^{\Gamma^*} C_j^{\Gamma} \langle \Phi(\gamma_i; \pi_i J_i) | \mathbf{T}^{\text{EMK}} | \Phi(\gamma_j; \pi_j J_j) \rangle \end{aligned} \quad (2.36)$$

Using Racah algebra techniques, these matrix elements between the CSFs are finally obtained as sums over radial integrals

$$\langle \Phi(\gamma_i; \pi_i J_i) || \mathbf{T}^{\text{EMK}} || \Phi(\gamma_j; \pi_j J_j) \rangle = \sum_{a,b} d_{ab}(i, j) \langle n_a \kappa_a || \mathbf{T}^{\text{EMK}} || n_b \kappa_b \rangle \quad (2.37)$$

where the d_{ab} are derived from the angular coefficients (2.21) described above. The above procedure assumes that the two atomic states Γ_i and Γ_j are built from the same set of optimized orbitals. When the orbitals are separately optimized for both states, the evaluation of this matrix element becomes very time consuming since the non-orthogonalities of the initial and final state orbital sets prevent Racah algebra to be used. For this case, the representation of the two states are changed in such a way that orbital sets become biorthonormal [74]. For the two states expanded in CSFs

$$\sum_i C^{\Gamma_i} \Phi(\gamma_i; \pi_i J_i) \quad \text{and} \quad \sum_j C^{\Gamma_j} \Phi(\gamma_j; \pi_j J_j), \quad (2.38)$$

the orbital sets $\{\phi_i\} \rightarrow \{\phi'_i\}$ and $\{\phi_j\} \rightarrow \{\phi'_j\}$ are transformed to a biorthonormal basis, i.e. $\langle \phi'_i | \phi'_j \rangle = \delta_{ij}$. The orbital transformation in effect changes the CSFs, and we have

$$\Phi(\gamma_i; \pi_i J_i) \rightarrow \Phi'(\gamma_i; \pi_i J_i) \quad \text{and} \quad \Phi(\gamma_j; \pi_j J_j) \rightarrow \Phi'(\gamma_j; \pi_j J_j). \quad (2.39)$$

The orbital transformation is followed by a counter-transformation of the expansion coefficients $\{C^{\Gamma_i}\} \rightarrow \{C'^{\Gamma_i}\}$ and $\{C^{\Gamma_j}\} \rightarrow \{C'^{\Gamma_j}\}$ so as to leave the wave functions invariant, i.e.

$$\sum_i C^{\Gamma_i} \Phi(\gamma_i; \pi_i J_i) \equiv \sum_i C'^{\Gamma_i} \Phi'(\gamma_i; \pi_i J_i),$$

and

$$\sum_j C^{\Gamma_j} \Phi(\gamma_j; \pi_j J_j) \equiv \sum_j C'^{\Gamma_j} \Phi'(\gamma_j; \pi_j J_j). \quad (2.40)$$

In the new representation standard Racah algebra can be used to evaluated transition matrix elements.

It is important to note that for the transition amplitude, the corrections which are mentioned in this Chapter improve only the wave functions and the energies

related to the states involved in the transition. However, for high precision calculations, sometimes we need to consider these corrections to the transition operator involved in the transition as well. We will explain in Chapter 3 in details that the QED correction to the transition operator has a significant effect on $M1$ transition. Similarly, in Chapter 4, we will demonstrate that nuclear recoil correction should also be considered to $E1$ transition operator for accurate transition rate calculation.

3 $M1$ forbidden transition in B-,Al-,F- and Cl-like ions

In this chapter, we shall present high precision calculations for the line strengths of magnetic dipole transitions between the $2s^22p\ ^2P_{3/2} - ^2P_{1/2}$ levels in B-like, the $3s^23p\ ^2P_{3/2} - ^2P_{1/2}$ levels in Al-like, the $2s^22p^5\ ^2P_{1/2} - ^2P_{3/2}$ levels in F-like and the $3s^23p^5\ ^2P_{1/2} - ^2P_{3/2}$ levels in Cl-like ions for the four elements argon, iron, molybdenum and tungsten [75]. These line strengths can be calculated very precisely because in non-relativistic theory these are independent of the wave function description. The calculated lifetimes of the respective upper states from these transition will lie in the millisecond to picoseconds range and may be used as a benchmark for comparison with the experiments.

This Chapter is structured in the following way: a short description of the $M1$ line strength in the non-relativistic limit is described in Sec. 3.1. In this section, we also describe how total line strength is obtained by adding higher-order corrections to non-relativistic line strength. Evaluation of the relativistic correlation corrections to the line strength is presented in Sec. 3.2. In Sec. 3.3, we evaluate the QED corrections to all orders in αZ . In Sec. 3.4, we present a detailed comparison of our calculated line strengths with other theories. Furthermore, adding the contributions from $E2$ channel for these transitions, we predict the lifetimes of the excited states of the ground configurations in B-, Al-, F- and Cl-like ions and compare with available experiments.

3.1 Theory - Basic formulas

The magnetic dipole transition probability from an upper state i to a lower state f is expressed in terms of the line strength as

$$A_{ij}^{M1} = \frac{4}{3} \frac{\omega^3}{c^3} \mu_0^2 \frac{S}{2J_i + 1}, \quad (3.1)$$

where μ_0 denotes the Bohr magneton, c is the speed of light, $\omega = E_i - E_f$ the transition energy and S is the line strength given as

$$S = \frac{18c^4}{\omega^2} |\langle \Psi_f \| \mathbf{T}^{M1} \| \Psi_i \rangle|^2. \quad (3.2)$$

\mathbf{T}^{M1} is the $M1$ transition operator given as

$$\mathbf{T}^{M1} = \frac{1}{\sqrt{2}} j_1(\omega r/c) \frac{[\boldsymbol{\alpha} \times \mathbf{r}]}{r} = \frac{\sqrt{2}}{r} j_1(\omega r/c) \boldsymbol{\mu}. \quad (3.3)$$

Here $\boldsymbol{\mu} = -[\mathbf{r} \times \boldsymbol{\alpha}]/2$ is relativistic magnetic moment operator, $\boldsymbol{\alpha}$ is Dirac matrix and j_1 is the spherical Bessel function.

In the non-relativistic limit the expansion of $j_1(\omega r/c)$ can be restricted to the first term, and this gives rise to the more familiar $M1$ transition operator

$$\mathbf{T}_{\text{nr}}^{M1} = -\frac{\sqrt{2}}{3} \frac{\omega}{c} \mu_0 (\mathbf{L} + 2\mathbf{S}). \quad (3.4)$$

where \mathbf{L} and \mathbf{S} are the orbital and spin angular momentum operators, respectively. In the LS -coupling scheme, which is realized in the non-relativistic case, the $M1$ line strength is nonzero only between fine-structure levels with $\Delta J = \pm 1$. The reduced matrix element of $\mathbf{T}_{\text{nr}}^{M1}$ within the LS -coupling is given by

$$\begin{aligned} \langle J_f \| \mathbf{T}_{\text{nr}}^{M1} \| J_i \rangle &= -\frac{\sqrt{2}}{3} \frac{\omega}{c} \mu_0 \langle J_f \| (\mathbf{J} + \mathbf{S}) \| J_i \rangle \\ &= -\frac{\sqrt{2}}{3} \frac{\omega}{c} \mu_0 \langle J_f \| \mathbf{S} \| J_i \rangle, \end{aligned}$$

which implies,

$$S_{\text{nr}} = |\langle J_f \| \mathbf{S} \| J_i \rangle|^2. \quad (3.5)$$

Therefore, in the non-relativistic limit the line strength S_{nr} is completely determined by the quantum numbers of the initial and final states and does not depend on the radial part of the many-electron wave functions of the initial and final states. For the $^2P_{1/2} - ^2P_{3/2}$ and $^2P_{3/2} - ^2P_{1/2}$, fine-structure transitions, the non-relativistic line strength results in the value of 4/3.

The total line strength can be calculated by adding different corrections to the

non-relativistic line strength as follows,

$$S = S_{\text{nr}} + \Delta S_{\text{D}} + \Delta S_{\text{CI,C}} + \Delta S_{\text{CI,B}} + \Delta S_{\text{QED}} + \Delta S_{\text{rec}}. \quad (3.6)$$

Here ΔS_{D} is the correction due to the relativistic motion of the electrons as described by the (single-electron) Dirac equation. This correction is calculated as a difference between line strength evaluated between Eq. (3.5) and Eq. (3.2). In Eq. (3.2) the initial and final state wave functions are linear combination of Slater determinants constructed in terms of one-electron Dirac wave functions which are the solution of the non-interacting one electron Dirac Hamiltonian.

The next two terms in Eq. (3.6) are due to the relativistic electron-electron interaction (correlations). While the first term $\Delta S_{\text{CI,C}}$ arises from the Coulomb interaction, and the second $\Delta S_{\text{CI,B}}$ occurs due to the Breit interaction. Both of these terms are evaluated in details in Sec. 3.2. The next correction ΔS_{QED} originates from QED diagrams, namely, the self-energy diagrams. It is calculated here to all orders in αZ . The evaluation of this term is described in Sec. 3.3.

Finally, ΔS_{rec} is the correction to the line strength due to the finite nuclear mass effect. This effect can be calculated only by using a rigorous QED approach as described by Volotka *et al.* [17]. According to this approach the recoil corrected magnetic moment operator is given by

$$\boldsymbol{\mu} = -\mu_0 \left(\mathbf{L} + 2\mathbf{S} - \frac{1}{M} \sum_{i,j} [\mathbf{r}_i \times \mathbf{p}_j] \right), \quad (3.7)$$

where M is mass of the nucleus. Hence the correction to the line strength due to the nuclear recoil can be written as

$$\begin{aligned} \Delta S_{\text{rec}} &\simeq -2 \langle J_f \parallel (\mathbf{L} + 2\mathbf{S}) \parallel J_i \rangle \\ &\times \langle J_f \parallel \frac{1}{M} \sum_{i,j} [\mathbf{r}_i \times \mathbf{p}_j] \parallel J_i \rangle. \end{aligned} \quad (3.8)$$

However, these contributions are very small at the present level of accuracy compared to the leading non-relativistic value $4/3$. For example ΔS_{rec} amounts to 0.000021, 0.000015, 0.000009 and 0.000005 for B-like Ar, Fe, Mo, and W ions, respectively. Therefore, we do not present these values in our final table of the various contribution to line strengths.

3.2 Correlation corrections

In order to evaluate the interelectronic correlation correction arising due to Coulomb interaction $\Delta S_{\text{CI,C}}$, we apply systematically enlarged many-electrons wave functions as described in details in chapter 2. In brief, we started our calculations with the lowest-order of approximation. For this the wave functions for the states with $J = 1/2$ and $J = 3/2$ are calculated within the basis of the multi-reference (MR) configurations. The CSFs in the MR set are generated from the configurations $\{1s^2 2s^2 2p, 1s^2 2p^3\}$, $\{1s^2 2s^2 2p^6 3s^2 3p, 1s^2 2s^2 2p^6 3p^3\}$, $1s^2 2s^2 2p^5$ and $1s^2 2s^2 2p^6 3s^2 3p^5$ for the B-, Al-, F- and Cl-like ions, respectively. After the initial calculations, the wave functions are systematically improved by performing MCDHF calculations using the active set approach described in Sec. 2.5. Here for each new layer of correlation orbitals the basis of CSFs is expanded by including further SD virtual excitations from the configurations defining the MR set to the active set of orbitals. The active set of orbitals is spanned by the orbitals with a principal quantum number $n \leq 7$ and with azimuthal quantum number $l \leq 6$.

Following each of the MCDHF calculations, separate RCI calculations are performed to further improve the initial and final state wave functions. These allowed us to evaluate the correction due to the Breit interaction $\Delta S_{\text{CI,B}}$ to the line strength. For these calculations the Dirac-Coulomb Breit Hamiltonian (2.28) is used.

The sum of these two corrections gives rise to the total relativistic correlation correction ΔS_{CI} . These contributions are presented in Table 3.1 as a function of the size of the increasing active set labeled by the highest principal quantum number n of the orbitals considered for the correlations. For the sake of brevity, we present the results only for the Fe ions. As seen from Table 3.1, the convergence with regard to the size of the active set is fairly achieved which allows us to set an absolute uncertainty for the correlation correction to a range 1×10^{-5} to 5×10^{-5} depending on the particular ion.

3.3 QED correction

The QED correction to the $M1$ line strength ΔS_{QED} can be derived in lowest order in αZ by modifying the $M1$ transition operator of the atomic magnetic moment for the EAMM, as discussed in details by Tupitsyn *et al.* [15]. The contribution of the

Table 3.1: Correlation correction ΔS_{CI} to the $M1$ line strength of the transition between the fine-structure levels of the ground configuration for B-, F-, Al- and Cl-like Fe ions. The MCDHF and RCI methods are employed to evaluate these corrections considering Coulomb and Breit type interactions. They are presented as a function of the size of the increasing active set (AS) labeled by the highest principal quantum number n of the orbitals starting from the MR set.

AS	B-like Fe	F-like Fe	Al-like Fe	Cl-like Fe
MR	0.00053	0.00154	0.00149	0.00167
3	0.00052	0.00146	0.00148	0.00165
4	0.00049	0.00151	0.00146	0.00164
5	0.00050	0.00153	0.00145	0.00164
6	0.00045	0.00146	0.00147	0.00165
7	0.00045	0.00145	0.00147	0.00164

EAMM amounts to $\Delta S_{\text{QED,EAMM}} = 0.00618$. Moreover, Volotka *et al.* [16] calculated the one-loop QED correction for several B-like ions to all orders in αZ within the so-called original Furry picture - and by taking into account only the Coulomb potential of the nucleus. We now consider an *extended* Furry picture which includes a local screening potential in the unperturbed Hamiltonian, and extend the calculations for F-, Al-, and Cl-like systems. This extension enables us to account partially for the screening QED corrections by evaluating only one-electron QED diagrams. In the extended Furry picture, we solve the Dirac equation with an effective spherically symmetric potential treating the interaction with the external Coulomb potential of the nucleus and the local screening potential exact to all orders. We employ here the core-Hartree screening potential, which is given by the expression

$$V_{\text{scr}}(r) = \int_0^\infty dr' \frac{1}{r_{>}} \rho_{\text{core}}(r'). \quad (3.9)$$

Here ρ_{core} denotes the total radial charge density distribution of the core electrons

$$\begin{aligned} \rho_{\text{core}}(r) &= \sum_c \left[P_c^2(r) + Q_c^2(r) \right], \\ \int_0^\infty dr \rho_{\text{core}}(r) &= n_c, \end{aligned} \quad (3.10)$$

where n_c is the number of the core electrons, i.e., $n_c = 4, 8, 12, 16$ for B-, F-, Al-, and Cl-like ions, respectively. This screening potential is generated self-consistently by solving the Dirac equation until the energies of the core and valence states become

Figure 3.1: Feynman diagrams that represent the self-energy correction to the line strength. The wavy line indicates the photon propagator and the double line indicates the bound-electron wave functions and propagators in the effective potential being the sum of Coulomb and screening potentials. The single photon emission is depicted by the wavy line with arrow.

stable with the relative accuracy of 10^{-9} . To estimate the sensitivity of the result on the choice of the potential several tests have been performed with other screening potentials: Kohn-Sham, Dirac-Hartree, and Dirac-Slater constructed for the initial as well as for the final state. It has been found out, that a relative difference between results obtained with different potentials does not exceed 5×10^{-4} . Overall, therefore, the uncertainty is dominated by a numerical error, which is everywhere smaller than 10^{-5} .

The one-loop QED correction to the line strength consists of the self-energy and vacuum-polarization terms. However, the vacuum-polarization correction previously evaluated in the Uehling approximation appears to be two – four orders of magnitude smaller than the self-energy correction beyond the EAMM approximation [76]. For this reason, we neglect the vacuum-polarization term in the present consideration. The self-energy contribution is given by the diagrams depicted in Fig. 3.1.

While the formulas derived by Volotka *et al.* [16] in the original Furry picture remain formally the same, let us remind that the Dirac spectrum is now generated by solving the Dirac equation with the effective potential. We make use of the implementation of Volotka *et al.* [16] who presented a detailed description of these calculations for B-like ions.

3.4 Results and discussion

Table 3.2 lists different corrections to the non-relativistic line strength for the $M1$ transition between the fine-structure levels of the ground configurations in B-like and F-like Ar, Fe, Mo and W ions. These corrections refer to two different systems of p subshells, one with a single valence electron and other with a single vacancy in the L shell. Table 3.3 shows similar results as Table 3.2 but for the M shell for Al-like and Cl-like Fe, Mo and W ions. As seen from Tables 3.2 and 3.3 the relativistic correction ΔS_D is most important.

Its value increases by an order of magnitude for the Mo and W ions when compared to Ar and Fe ions. The correlation correction arising due to Breit interaction turns out to be relatively small as compared to corrections arising due to Coulomb interaction. For Mo and W ions these corrections provide essential contributions to the total line strengths. The next important correction arises from the self-energy (QED). Generally, the lowest order QED correction i.e., the inclusion of EAMM to the transition operator, is considered enough for such type of transitions. As discussed in sections 3.3 this correction amounts to 0.00618 the total line strength. However, the present estimates of the QED correction show that the inclusion of the EAMM is enough only for low Z . For the heavier systems the present rigorous calculations of QED corrections within an extended Furry picture approach are necessary. Finally, all corrections sum to the total line strength S . In order to estimate the total uncertainty we have to note here that the contribution of the negative-energy excitations is not taken into account in present calculations. Since the value of the negative-continuum term strongly depends on an employed one-electron basis functions [15] varying them we estimate its contribution to be less than half of the correlation effect. The uncertainties of individual terms presented in Tables 3.2 and 3.3 as discussed above in corresponding subsections are much smaller than the uncertainty due to the negative-continuum contribution. Therefore, the total uncertainty of the line strength S obtained is fully determined by missing negative-continuum contribution.

In order to compare our results with previous computations, we make use of the line strength from $M1$ transition rates based on Eq. (3.1). We took the same transition energies that have been used in respective calculations. It should be noted that we have added the QED contribution to the line strengths in respective theoretical values wherever this effect has not been considered. For B-like Ar, which

Table 3.2: Individual corrections to the $M1$ non-relativistic line strength $S_{\text{nr}} = 4/3$ for the $(2s^22p) \ ^2P_{1/2} - \ ^2P_{3/2}$ transition in B-like as well as for the $(2s^22p^5) \ ^2P_{3/2} - \ ^2P_{1/2}$ transitions in F-like Ar, Fe, Mo and W ions. The total line strength (S) is compared with other theories. The uncertainties involved in the calculation of line strengths are given within the parentheses.

has received much attention over the last decade, our result of total line strength 1.33714(28) corroborates the two exceptionally agreeing calculations from Tupitsyn *et al.* [15] and from Froese Fisher *et al.* [20]. Tupitsyn *et al.* [15] reported the line strength value 1.33693(26) for B-like Ar. Additionally, Froese Fisher *et al.* [20] reported a line strength 1.3372 for B-like Ar. Froese Fisher *et al.* [20] further extended their calculations for the B-like isoelectronic sequence until $Z = 42$. As seen from Table 3.2 our results also agree with B-like Fe and B-like Mo. Our results of the line strengths for all other systems under present study are in agreement with other available theories. The only exception is with the relativistic coupled-cluster calculations of Nandy [77] for which the line strength of 1.356(5) in F-like Ar is overestimated and the line strength of 1.3270 in F-like Fe of Nandy and Sahoo [82] is underestimated. This may be due to the incorrect handling of intruder states in the implementation of coupled-cluster theory in open shell systems [87]. Overall, our calculations have reached an accuracy of $10^{-4} - 10^{-5}$ for the QED sensitive $M1$ line strengths between the fine structure levels of the same configuration. As a result, the present calculations provide a theoretical prerequisite for a test of QED effects in the line strengths of various ions.

In Table 3.4 we present the lifetimes τ_{pres} (in seconds) calculated for the $(2s^22p) \ ^2P_{3/2}$ level in B-like ions, the $(2s^22p^5) \ ^2P_{1/2}$ level in F-like ions, the $(3s^23p) \ ^2P_{3/2}$ level in Al-like ions as well as for the $(3s^23p^5) \ ^2P_{1/2}$ level in Cl-like ions. Here, τ_{exp} are experimental lifetimes and respective experimental uncertainties are given in parentheses. A^{M1} is the present transition rate from the $M1$ channel. We used the best available transition energies from the literature for the calculation of the transition rate. For B-like ions we applied the transition energies from the rigorous QED treatment of Artemyev *et al.* [8, 10], and for the rest of the ions we used transition energies from the NIST database [88]. Here A^{E2} is the transition rate from the $E2$ channel in length form. For the $E2$ transition rate, we make use of the same wave function expansion as for the $M1$ transition rate, in addition to that the length and the velocity gauges of the $E2$ line strength were in good agreement. Let us note that the present uncertainties in transition rates and lifetimes are due to uncertainties in the calculation of the $M1$ line strengths only. They are given within the parentheses. For the present level of accuracy, the uncertainties due to the $E2$ transition channel are very small. However, the uncertainties in the transition energies will increase total uncertainties in our calculations accordingly.

Table 3.4: Lifetimes τ_{pres} (in seconds) calculated for the $(2s^22p) \ ^2P_{3/2}$ level in B-like ions, the $(2s^22p^5) \ ^2P_{1/2}$ level in F-like ions, the $(3s^23p) \ ^2P_{3/2}$ level in Al-like ions and the $(3s^23p^5) \ ^2P_{1/2}$ level in Cl-like ions compared with experimental lifetimes (τ_{exp}). A^{M1} is the present transition rate (in s^{-1}) from the $M1$ channel and A^{E2} is the transition rate (in s^{-1}) from the $E2$ channel. The values of the transition energy used for the present lifetime calculations are given in cm^{-1} and corresponding transition wavelengths λ in \AA . The uncertainties involved in the calculation of transition rate and lifetime arising due to uncertainties in the line strengths are given within the parentheses. The numbers given in the square brackets denote powers of 10.

⁹HD-EBIT experiment by Brenner *et al.* [95].

¹⁰TSR measurements at the Max Planck Institute for Nuclear Physics, Heidelberg, Germany by Träbert *et al.* [96].

As seen from Table 3.4, our predicted lifetimes for B-like Ar and for Al-like Fe disagree with both experiments at the HD-EBIT [13, 14]. In contrast, the comparison of our predicted lifetime for F-like Ar with the experiment at the LLNL-EBIT [91] and for the lifetime of Cl-like Fe with the experiment at the HD-EBIT [95] shows very good agreement. For Cl-like Fe, our lifetime also agrees well with the extrapolated lifetime of Träbert *et al.* [96] which is resulted in an experimental study along Cl-like Co, Ni and Cu ions. These experiments with an uncertainty larger than 0.5% are however not sensitive enough to test the underlying relativistic correlations and the leading QED effects. New experiments with the soft x-ray free electron laser (FLASH) and a new EBIT [97] along with the pump probe x-ray laser experiments [26] are hopeful to provide experimental data for the transitions with short lifetimes in so far inaccessible energy ranges. We believe that our calculations will support such future experiments for transitions with different frequencies and lifetimes.

4 $E1$ dipole allowed transition in Be-like carbon

In this chapter, we shall present a detailed calculation of the line strength of the $1s^2 2s 2p \ ^1P_1 - 1s^2 2s^2 \ ^1S_0$ transition in Be-like carbon in the prospect of high precision experiment [98]. This transition within the same shell ($\Delta n = 0$) and in the low charge state of the ion is highly correlated. Therefore, we develop various electron correlation models and use orthogonal and nonorthogonal set of orbitals for the initial and final states in these correlation models. Generally, the $E1$ line strength is computed with two operators, referred to as the Babushkin and the Coulomb form, which in the non-relativistic limit correspond to the length and velocity form. In this thesis, we will refer to them as length and velocity form, respectively. We shall discuss that the accuracy assessment based only on an agreement between the gauges might be overestimated. For this reason, we shall estimate the uncertainty from the differences between the results obtained within all the correlation models that are developed in present work. Moreover, we shall demonstrate that the gauge invariant finite nuclear mass effect to the line strength is achieved after taking into account the recoil correction to the transition operator.

The following parts of the chapter are structured as follows. In Sec. 4.1, we present a brief introduction of the experimental proposal for CRYRING at ESR (at GSI Darmstadt). In Sec. 4.2 we present the underlying theory for calculation of the line strength. A detail of the correlations models and results obtained are explained in Sec. 4.3. In Sec. 4.4, we present theoretical methods for the finite nuclear mass effect. In the final section of this Chapter, we compare and discuss the obtained results with other theories and experiments.

4.1 Experimental proposal for CRYRING at ESR

A schematic diagram of the proposed pump-probe experiment is shown in Fig 4.1. The system is excited from the ground state to a short-lived excited state by the pump pulse via a dipole $E1$ transition. The population of this excited state is then probed by photoionization with a second temporally delayed probe pulse. By

measuring the ionization signal (changed charge state) via the delay of both pulses the excited state lifetime can be determined. A first experiment on the Be-like carbon ions has been proposed to be performed at CRYRING at GSI Darmstadt [27]. Here the photon energy of both pulses is in the XUV spectral region. The pump and the probe pulses will be delivered by a table-top XUV source based on high harmonic generation [99]. By splitting the pulses delivered by a high repetition

Figure 4.1: Scheme of a pump-probe experiment for atomic lifetime measurements of the $1s^2 2s 2p \ ^1P_1$ state in Be-like carbon. At time t_1 the XUV-pump pulse excites the $1s^2 2s^2 \ ^1S_0$ ground state of the Be-like carbon sample to the $1s^2 2s 2p \ ^1P_1$ excited state. The population $n(t)$ of the excited state 1P_1 decays then exponentially. A second and temporally delayed XUV-probe pulse probes the rest population of the excited state at time t_2 by ionizing Be-like carbon ion and maps out the exponential curve from which the decay rate is determined.

Figure 4.2: Schematic drawing of a XUV-pump XUV-probe experiment on Be-like carbon ions at CRYRING at GSI Darmstadt.

rate femtosecond laser system, two well synchronized pulses will be generated and subsequently frequency-converted to the XUV via high harmonic generation in two gas jets, as illustrated in Fig 4.2. The overlap of ion beam and laser beams will be ensured by scrapers along a ~ 3 m long interaction region. The changed charge

state of the ions will finally be detected by a particle detector within the subsequent dipole magnet. Within the frame of the ions, which move anticollinearly to the XUV pulses, the photon energy can be effectively tuned onto resonance via Doppler tuning [100]. In this way, the transition energy can be measured as well.

The pump-probe measurement promises to reach ~ 100 fs absolute and 10^{-4} precision with a few-ns delay line and thus will provide novel sensitive tests for state-of-the-art atomic structure calculations. Note that the high energy storage ring (HESR) at the future FAIR facility will provide relativistic ion beams with a Doppler-shift up to an order of magnitude. Thus, similar experiments can be performed with a large variety of highly-charged ions including H-, He-, Li- and Be-like ions.

4.2 Basic formulas

The electric dipole transition probability from an upper state k to a lower state j is expressed in terms of the line strength as

$$A_{kj}^{E1} = \frac{4}{3} \frac{\omega^3}{c^3} \frac{S}{2J_k + 1}, \quad (4.1)$$

where c is the speed of light and ω the transition energy between the two states. The line strength S is square of the reduced non-diagonal matrix element (2.35) given as

$$S = |\langle \Psi(\Gamma_k; \pi_k J_k) | \mathbf{T}^{E1} | \Psi(\Gamma_j; \pi_j J_j) \rangle|^2, \quad (4.2)$$

Here, \mathbf{T}^{E1} is $E1$ transition operator [59]

$$T_M^l = \frac{\sqrt{2\pi}c}{\omega} \sum_i^N \left[-\sqrt{6}j_1(\omega r_i/c) Y_{1M}(\mathbf{n}_i) + 3j_2(\omega r_i/c) c\boldsymbol{\alpha}_i \cdot \mathbf{Y}_{1M}^2(\mathbf{n}_i) \right], \quad (4.3)$$

in the length gauge and

$$T_M^v = \frac{\sqrt{2\pi}c}{\omega} \sum_i^N \left[-\sqrt{2}j_0(\omega r_i/c) c\boldsymbol{\alpha}_i \cdot \mathbf{Y}_{1M}^0(\mathbf{n}_i) + j_2(\omega r_i/c) c\boldsymbol{\alpha}_i \cdot \mathbf{Y}_{1M}^2(\mathbf{n}_i) \right], \quad (4.4)$$

in the velocity gauge. Here, ω is the transition energy, Y_{JM} are the spherical harmonics, \mathbf{Y}_{JM}^L are the spherical vectors, and $j_J(\omega r/c)$ is the spherical Bessel function. In order to investigate the dependence of the line strength on the transition energy we expand the Bessel functions $j_J(\omega r/c) \approx (\omega r/c)^J/(2J+1)!!$, so called the long-wavelength approximation $\omega/c \ll 1$, and retain only the leading term in the power series expansion. In such a way the line strength takes a form:

$$S^l \approx \left| \left\langle \Psi(\Gamma_k; \pi_k J_k) \left| \sum_i^N \mathbf{r}_i \right| \Psi(\Gamma_j; \pi_j J_j) \right\rangle \right|^2, \quad (4.5)$$

in the length gauge and

$$S^v \approx \frac{c^4}{\omega^2} \left| \left\langle \Psi(\Gamma_k; \pi_k J_k) \left| \sum_i^N \boldsymbol{\alpha}_i \right| \Psi(\Gamma_j; \pi_j J_j) \right\rangle \right|^2, \quad (4.6)$$

in the velocity gauge. From the expressions (4.5) and (4.6) one can see, that the leading terms of the line strength in the length form is insensitive to transition energy whereas in the velocity form it is proportional to ω^{-2} . Based on these observations one can introduce the semi-empirical correction to the line strength in the velocity gauge by adjusting the transition energy to a more accurate, e.g., experimental, value, i.e., $\Delta S^v = (\omega^2 - \omega_{\text{exp}}^2)/\omega_{\text{exp}}^2 S^v$. Such a correction allows to take partially into account the missing correlation contributions. The line strength in the velocity gauge adjusted in this way $S_{(\text{exp})}^v$ is typically much closer to the value in the length gauge S^l . Generally, the gauge invariance should be restored when all correlation effects are taken into account, both for the transition matrix element and transition energy, which was explicitly demonstrated in the framework of the relativistic many-body perturbation theory [101] and QED formalism [102]. In view of this, the excellent agreement between the gauges after adjustment suggests that the remaining unaccounted correlation effects to the transition amplitude are rather small. As a result, the difference between the line strengths calculated in the length gauge and adjusted value in the velocity gauge is employed for the theoretical error estimation [103, 104]. However, it is still possible that the remaining unaccounted correlation effects bring not only the identity in the gauges, but also a shift to both the values an amount much larger than the difference between the gauges after adjustment.

4.3 Correlation models

In a view of an absence of strong criteria for the uncertainty estimation of the calculated line strength, we performed the MCDHF calculations for different correlations models. Among those models, we choose only four models based on the accuracy criterion for the transition energy as it is compared with the experimental energy as well as the agreement between the two gauges of the line strength. These four models were based on a separate and simultaneous (orthogonal and nonorthogonal) set of orbitals for the ground and excited states. In each model, the correlations were incorporated by systematically extending the calculations as describes in Sec. 2.5. Here the reference configurations for the first three models were $\{1s^22s^2, 1s^22p^2\}$ for the 1S_0 ground state and $\{1s^22s2p\}$ for the 1P_1 excited state. For the fourth model, the reference configurations were increased and we explain its details later in this section. The calculations were extended by expanding the basis set of CSFs using the active set approach as describes in Sec. 2.5.

We now explain how valence-valence (VV), core-valence (CV) and core-core (CC) correlations were incorporated. We started to expand the basis set by adding the CSFs that are generated from the configurations $1s^2nl n'l'$ which are resulted from SD excitations from outer shells of the reference configuration. These CSFs account VV correlations and the calculations are named as VV calculations. To each layer of VV correlation calculations, we then added CSFs of the configurations $1s2snln'l' + 1s2pnln'l'$ which arise from the single excitation from the $1s^2$ core with or without another excitation from the valence shells. These added CSFs account for the CV correlations and the calculations are called VV+CV. Now with each layer of VV+CV correlation calculations, the correlations of two-electron excitations from the $1s^2$ core were included to account for the CC correlations. These additional CSFs arise from the configurations $2s^2nl n'l' + 2p^2nl n'l'$ for the 1S_0 state and $2s2pnln'l'$ for the 1P_1 state. These correlation calculations are named as VV+CV+CC calculations. In all VV, VV+CV and VV+CV+CC calculations, the active set of orbitals was spanned by the orbitals with principal quantum number $n, n' \leq 15$ and with azimuthal quantum number $l, l' \leq 7$. Finally, the basis set of CSFs was expanded by appending CSFs with configurations arising from SDTQ excitations from the reference configurations. In the SDTQ excitations the number of CSFs increased very rapidly with the increasing number of orbitals in the active set which limits the numerical stability and available hardware resources. So the SDTQ excitations

were limited only with $n, n' \leq 5$ and $l, l' \leq 4$. These calculation were then extended with SD excitations with remaining layer of correlation orbitals with $n, n' \leq 15$ and $l, l' \leq 7$. We name these final set of calculations as VV+CV+CC:SDTQ.

4.3.1 Model 1

In this model the VV and VV+CV calculations were performed by utilizing the OL scheme for the ground and excited state, i.e., for both states orbitals were separately optimized, whereas for the VV+CV+CC as well as VV+CV+CC:SDTQ calculations the spectroscopic orbitals and the correlation orbitals with $n = 3$ were simultaneously optimized using the EOL scheme. Then the calculations after $n = 3$ were extended with a separate set of correlation orbitals (the OL scheme). This model accounts for the correlations in a similar manner as those presented by Jönsson and Froese Fischer [32]. The only difference is that Jönsson and Froese Fischer performed VV+CV+CC:SDTQ calculations with SDTQ excitation until $n = 3$ only and extended their calculations from $n > 3$ with VV+CV type of correlations only.

In Fig. 4.3 (upper plot) we compare the present calculations of Model 1 with Jönsson and Froese Fischer results in [32]. The line strength in length and velocity form is plotted against increasing n of the active set size defining the wave function expansion in respective calculations. It is clearly evident that their two gauges agree perfectly at $n = 8$ once the experimental energy adjustment was applied. Explicitly, the line strength calculated by Jönsson and Froese Fischer [32] amounts to 2.4376 in the length gauge and 2.4366 in the velocity gauge after adjustment, which leads to a tabulated final value 2.4376(13). Despite we cannot explicitly reproduce these calculations, our evaluations show the similar effect at $n = 7$ active set layer, where the results obtained in the length and velocity (adjusted) gauges approach each other. However, when the active set size is further extended, one can clearly see that after $n = 7$ layer the results first drift apart and then, again, approach each other but at some different position. These observations lead us to the following conclusions. First, the agreement between gauges might be of an accidental character and, therefore, second, the difference between results in the length and velocity (adjusted) gauges should be very carefully used as a criterion for the error estimation.

Let us mention here another important observation. From the basic theory

Figure 4.3: Comparison of the line strengths evaluated according to the Model 1 (TW) as a function of active set size of the orbitals with the results of Jönsson and Froese Fischer [32]. The green circles, red down triangles, and blue upper triangles display the present calculations in the length gauge S^l as well as in velocity gauges before S^v and after adjustment S^v_{exp} to the experimental transition energy ω_{exp} , respectively. The green hollow squares, red hollow diamonds, and blue hollow stars are corresponding values taken from Ref. [32].

[101, 102], it is clear that the adjustment should be made to the transition energy which corresponds to the difference of the eigenvalues of the Dirac-Coulomb Hamiltonian in Eq. (2.3). Therefore, we calculate a so-called experimental-Dirac-Coulomb transition energy $\omega_{\text{exp-DC}}$ as a difference of the experimental value ω_{exp} and the contributions beyond the Dirac-Coulomb approximation, i.e., the Breit interaction, recoil, and QED corrections. The $\omega_{\text{exp-DC}}$ energy is, thus, experimentally deduced fully correlated Dirac-Coulomb transition energy. At this end, we compare

Table 4.1: Transition energies ω (cm^{-1}) and line strengths S (a.u.) for the $1s^2 2s 2p \ ^1P_1 - 1s^2 2s^2 \ ^1S_0$ transition in Be-like carbon as functions of the active set calculated within Model 1. The line strengths in the length gauge (S^l) are compared with those in the velocity gauge *ab initio* calculated (S^v) and after adjustment to the experimental energy ω_{exp} ($S^v_{(\text{exp})}$) and to the experimental-Dirac-Coulomb energy $\omega_{\text{exp-DC}}$ ($S^v_{(\text{exp-DC})}$). The experimental transition energy is taken from Ref. [88], while the experimental-Dirac-Coulomb energy is evaluated by subtracting the Breit, recoil, and QED corrections from the experimental transition energy.

in Table 4.1 as well as in Fig. 4.3 (lower plot) the line strengths in the length gauge (S^l) and in the velocity gauge (*ab initio*) (S^v) with the adjusted to ω_{exp} ($S^v_{(\text{exp})}$) and to $\omega_{\text{exp-DC}}$ ($S^v_{(\text{exp-DC})}$) values. As one can see from this comparison the values adjusted to the experimental-Dirac-Coulomb energy are much close to the results in the length gauge. In particular, for $n = 15$ layer the relative difference between the gauges amounts to 2×10^{-5} . However, as we have mentioned at the end of Sec. 4.2 that the agreement between the gauges cannot be uniquely used for the accuracy assessment. For this reason, in the next subsections, we investigate also

other correlation models.

4.3.2 Model 2

Within this model, both the spectroscopic and the correlations orbitals were separately optimized using the OL scheme for all type of correlations. Hence generated orbitals for both states were not quite orthogonal with each other, which makes the implementation of standard Racah algebra difficult for the calculation of transition amplitude. To deal with this complication, a transformation to a biorthonormal basis was applied together with the counter transformation of the expansion coefficients as explained in Sec. 2.7.

Figure 4.4: Extent of different correlations effects to the transition energy with respect to the increasing n of the active set size defining the wave function expansion for the Model 2 calculations. The green circles represent VV correlations, magenta down triangles represent VV+CV, blue upper triangles represent VV+CV+CC, red-pentagons represent VV+CV+CC:SDTQ correlations. Please see the text for the details of different type of the correlations.

The calculations within this model show the importance of a common set of orbitals for the core correlations in the framework of MCDHF approach. For the CC effects, it is commonly accepted that these are more balanced if a common orbital basis is used for describing both the states involved in the transition and hence resulting transition energies are more accurate [105, 106]. This is also obvious from Fig. 4.4 where the evaluation of different correlations effects to the transition energy are shown with respect to the increasing n of the active set size defining

the wave function expansion for the Model 2 calculations. Here the blue upper triangles representing VV+CV+CC correlation results are worse than the magenta down triangles representing VV+CV correlations. However, it is obvious from the red-pentagons representing VV+CV+CC:SDTQ in Fig. 4.4 that we get the best agreement of the transition energy with the experiment when the TQ excitations are included with SD excitations in the CC correlations. The difference of the final values of the energy of VV+CV+CC:SDTQ calculations with Model 1 and Model 2 is only 0.004%, whereas the length form of the line strength from both models varies only by 0.01%. The fact that TQ contributions are very important is also noticed from the results of Chen, Cheng and Johnson [35] who have also used TQ excitations in building a common set of orbitals in their RCI calculations based on B-spline basis.

4.3.3 Model 3

Within this model, both the spectroscopic orbitals and correlations orbitals were simultaneously optimized for the ground and excited states using the EOL scheme for all type of correlations. The so obtained orbitals for both states were orthogonal to each other. As it has been highlighted by Chen, Cheng and Johnson [35] and Savukov [36] that small orbital overlap corrections due to a non-diagonal set of orbitals for the initial and final states should not be ignored. Our correlation Model 3 helps to address this issue.

4.3.4 Model MR

In this model, the set of spectroscopic reference configurations were expanded to account the missing correlations due to limited SDTQ excitations. We name it as multi-reference (MR) model. The configurations in MR were expanded in such a way that the CSFs for the MR set had the largest expansion coefficients in the wave functions that were generated by VV+CV+CC:SDTQ calculations of Model 3. For the 1S_0 ground state the resulting MR set was $\{1s^22s^2, 1s^22p^2, 1s^23p^2, 2s^23s^2, 2s^23p^2, 1s^23d^2\}$ and for the 1P_1 excited state the resulting MR set was $\{1s^22s2p, 1s^22p3d, 2s2p3s^2, 2s2p3p^2\}$. All the orbitals occupied in MR set were spectroscopically treated in the lowest order of approximation. Then the correlation orbitals were treated in the same way as those of Model 3 using the

EOL scheme.

4.3.5 Models: summary

Our approach with either a common or two separate set of orbitals for the ground and excited states combines the strengths and weaknesses of the previous calculations which provide the uncertainty of the order of 10^{-3} [32, 35, 36]. The orbitals in the common set for both states are orthogonal to each other and there is no orbital overlap for the evaluation of the transition amplitude. At the same time, our procedure of two different sets of orbitals for each state has the advantage that the electron relaxation effects are automatically included to a large extent.

Figure 4.5: Convergence of transition energy with respect to the increasing n of the active set size defining the wave function expansion for the VV+CV+CC:SDTQ calculations of different correlation models. Please see the text for the details of the VV+CV+CC:SDTQ calculations.

In all our correlation models the overall convergence trends and behavior of the inner and outer electron correlations are consistent with each other. In Fig. 4.5 we present the convergence of the transition energy with respect to the increasing n of the active set size defining the wave function expansion for the VV+CV+CC:SDTQ calculations from all the correlation models under present study. For the Model 3 and MR we could not get the converged orbitals for $n = 15$. The first three models vary just with a difference of maximum of 6 cm^{-1} . But for Model MR we get 15 cm^{-1} better results and this is obvious due to the inclusion of higher-order correlations in

Figure 4.6: Line strength for the for the VV+CV+CC:SDTQ calculations from the Model 2, Model 3 and Model MR plotted similarly as that of Fig. 4.3. In each sub-figure, the green circles are the line strength S^l in length form, red down triangles are *ab initio* S^v velocity from, blue upper triangles are $S^v_{(exp)}$ velocity form adjusted the experimental transition energy ω_{exp} and black squares are $S^v_{(exp-DC)}$ velocity from adjusted the experimental-Dirac-Coulomb transition energy ω_{exp-DC} (see text).

this model.

In Fig. 4.6 we present the line strength for the VV+CV+CC:SDTQ correlations calculated within Model 2, 3, and MR in a similar way as explained in Sec. 4.3.1 and Fig. 4.3 (lower plot). From these plots, one can clearly see that in all models the line strength in the velocity adjusted to the experimental-Dirac-Coulomb energy agrees with the length gauge result much better than the adjusted to the pure experimental energy. This also confirms our expectations originated from the basic principles as stated at the end of Sec. 4.3.1. In order to get the final (Dirac-Coulomb) line strength value the results of the length gauge and adjusted to the experimental-Dirac-Coulomb energy velocity gauge obtained at the maximum active set size are analysed.

Figure 4.7: Line strength of the $1s^2 2s 2p \ ^1P_1 - 1s^2 2s^2 \ ^1S_0$ transition in Be-like carbon plotted against the present Models. Green squares represent to the length forms and blue circles to the velocity forms. The black solid line is the average of the both length and velocity forms. The gray shaded region is one standard deviation from the black line.

The employed data from all the correlation models are summarized in Table 4.2 and Fig. 4.7. As one can see from these data, despite the extraordinary agreement between gauges, e.g., in Model 1, one cannot use it for the uncertainty estimation. The reason for this has been explained at the end of Sec. 4.2 and confirmed now by the calculations in other models, which predict the quite larger spread of the results than given by the difference of the gauges. We use these scatter of the line strength data to predict the final value of the line strength accounting only the correlations

Table 4.2: ω is the Dirac-Coulomb transition energy (cm^{-1}). S^l and $S_{(\text{exp-DC})}^v$ are the Dirac-Coulomb line strengths in the length gauge and in the velocity gauge adjusted to $\omega_{\text{exp-DC}}$ energy (see text), in a.u.

Label	ω	S^l	$S_{(\text{exp-DC})}^v$
Model 1	102426	2.43843	2.43837

as 2.43851(37). It is represented in Fig. 4.7, as the black solid line which is average of all the values plotted. We find rather conservative to assess the uncertainty as one standard deviation of the scattered data. It is shown as a gray shaded region in Fig. 4.7. Such kind of an error estimation is further supported by the fact that it covers all the values obtained in the length gauge, which is known to be more reliable.

4.4 Nuclear recoil correction

Once the line strength is calculated, including all the major correlation contributions, the finite nuclear mass (nuclear recoil) contribution was added as a correction given as

$$\Delta S_{\text{rec}} = \Delta S_{\text{rec,en}} + \Delta S_{\text{rec,wf}} + \Delta S_{\text{rec,op}}, \quad (4.7)$$

where the first two terms on the right side in Eq. (4.7) are the corrections in the line strength due change in energy and wave functions, respectively, causing due to the nuclear recoil effect. These corrections were calculated by correcting the Dirac-Coulomb Hamiltonian (2.3) for lowest order nuclear motional corrections of NMS and SMS as described in Sec. 2.6.3.

It is also important, however, to take into account the recoil correction to the transition operator, i.e., the third term in Eq. (4.7). Previously, it was considered in many studies [107–110] for the $E1$ transitions and for the $M1$ -decay [17]. Starting from the non-relativistic Hamiltonian for N electrons and the nucleus, we obtain

the following recoil corrections to the $E1$ transition operator:

$$\Delta \mathbf{T}_{\text{rec}}^l = -\frac{Z-N}{M+N} \sum_{i=1}^N \mathbf{r}_i \quad (4.8)$$

in the length gauge and

$$\Delta \mathbf{T}_{\text{rec}}^v = -\frac{Z}{M} \frac{1}{\omega} \sum_{i=1}^N \mathbf{p}_i \quad (4.9)$$

in the velocity gauge. From these expressions one can easily come to the corresponding corrections to the line strength

$$\begin{aligned} \Delta S_{\text{rec,op}}^l &= 2\text{Re} \left\{ \langle \Psi(\Gamma_k; \pi_k J_k) | | \mathbf{T}^l | | \Psi(\Gamma_j; \pi_j J_j) \rangle \right. \\ &\quad \times \left. \langle \Psi(\Gamma_k; \pi_k J_k) | | \Delta \mathbf{T}_{\text{rec}}^l | | \Psi(\Gamma_j; \pi_j J_j) \rangle \right\} \\ &\approx 2 \frac{Z-N}{M} S^l \end{aligned} \quad (4.10)$$

and

$$\begin{aligned} \Delta S_{\text{rec,op}}^v &= 2\text{Re} \left\{ \langle \Psi(\Gamma_k; \pi_k J_k) | | \mathbf{T}^v | | \Psi(\Gamma_j; \pi_j J_j) \rangle \right. \\ &\quad \times \left. \langle \Psi(\Gamma_k; \pi_k J_k) | | \Delta \mathbf{T}_{\text{rec}}^v | | \Psi(\Gamma_j; \pi_j J_j) \rangle \right\} \\ &\approx 2 \frac{Z}{M} S^v. \end{aligned} \quad (4.11)$$

In Table 4.3 different recoil contributions due to the energy, wave functions, and

Table 4.3: The recoil corrections to the line strength originated from the energy and wave functions change, $\Delta S_{\text{rec,en+wf}}$, as well as due to the transition operator $\Delta S_{\text{rec,op}}$ calculated in the length and velocity gauges. The total gauge invariant recoil correction is presented in the last line. The values are in a.u.

Rec. correction	length	velocity
$\Delta S_{\text{rec,en+wf}}$	0.00000	-0.00089
$\Delta S_{\text{rec,op}}$	0.00045	0.00134
Total	0.00045	0.00045

the operator are presented in the length and velocity gauges. Only after adding the term due to the change of the operator the total recoil correction starts to be gauge invariant. In view of this, we would recommend to introduce this contribution also

to a next GRASP update.

4.5 Results and discussion

With the discussion above, we can obtain the final value of the line strength. In order to do so, we add to the Dirac-Coulomb value 2.43851(37) from Sec. 4.3 the recoil correction $\Delta S_{\text{rec}} = 0.00045$ calculated in the previous section. In addition, we have to consider also other effects, such as the Breit interaction as well as QED. The Breit contribution has been calculated as follows. The frequency-independent Breit Hamiltonian has been added to the Dirac-Coulomb Hamiltonian given by Eq. (2.3). Then the RCI calculations have been performed within the correlation Model 1. Comparing further the obtained results with the corresponding Dirac-Coulomb values we get for the Breit contribution ΔS_{Breit} 0.00030 and -0.00001 in the length and velocity gauge, respectively. Based on an analysis of the Breit contribution in the intercombination transition $2s2p\ ^3P_1 - 2s^2\ ^1S_0$ in Be-like carbon [35] and on arguments presented in [111, 112], we attribute this difference to a consequence of the employed no-pair approximation. That means that the gauge invariance of the Breit contribution will be restored when the negative-energy states will be taken into account. On another hand, it was demonstrated [111, 112], that the negative-continuum affects dominantly only the result in the velocity gauge, while the result of the length gauge remains stable. In view of this, we add the Breit correction, $\Delta S_{\text{Breit}} = 0.00030$, calculated in the length gauge to our final value. The remaining QED correction is estimated as $\alpha(\alpha Z)^2 \ln(\alpha Z)^{-1}$ [113, 114] to be 4×10^{-5} , which is much smaller than our uncertainty. As a result, our final value for the line strength reads 2.43926(37).

Once the line strength is calculated, it is straightforward to get the oscillator strength:

$$gf = \frac{2}{3}\omega S, \quad (4.12)$$

where g is the weight of upper state, and the lifetime of the $1s^2 2s2p\ ^1P_1$ excited state:

$$\tau = \frac{1}{A_{ij}^{E1}}. \quad (4.13)$$

Figure 4.8: A comparison of the present line strength of the $1s^2 2s 2p \ ^1P_1 - 1s^2 2s^2 \ ^1S_0$ transition in Be-like carbon with other theories and experiment.

Table 4.4: Comparisons between different calculations and experiments for the line strength of the $1s^2 2s 2p \ ^1P_1 - 1s^2 2s^2 \ ^1S_0$ transition and the lifetime of the $1s^2 2s 2p \ ^1P_1$ excited state in Be-like carbon.

Here the conversion to the lifetime from the line strength and vice versa is performed by using the experimental energy, $\omega = 102352.04 \text{ cm}^{-1}$ [88]. We note that the present uncertainty in the lifetime is only due to calculated line strength, since the uncertainty of the transition energy is expected to be much better than 1 cm^{-1} and this is far below the uncertainty of the line strength.

Fig. 4.8 and Table 4.4 compare the present results of calculated line strength and lifetime with other theories and experiments. Note that in the respective papers the values of oscillator strength is provided. We have converted the oscillator strength to the line strength using the energies mentioned in the respective papers. In Fig. 4.8, the experimental line strength reported by Reistad and Martinson [120] is plotted as a function of the experimental energy taken from the NIST database [88]. It is clear from Fig. 4.8 that our calculated energy is the closest to the experimental one. The present line strength or lifetime agrees very well with the CI+MBPT calculation of Savukov [36] and is in a fair agreement with the large-scale MCDF calculation of Jönsson and Froese Fischer [32] and the CI result of Chen, Cheng and Johnson [35].

It is obvious from the Table 4.4 that all the theoretical lifetimes except of Safronova *et al.* [34] are inside the error bar of the best available experimental lifetime of $0.569(10) \text{ ns}$ [120]. However, the uncertainty of this measurement is still too large to distinguish between different theories. Therefore, we hope that the proposed experiment [27] will provide a new benchmark for testing the theories in the case of Be-like carbon.

5 $E1$, $M1$, $E2$ and $M2$ transitions in Cl-like Ni

In this chapter, we shall present a detailed computation of transition rates, oscillator strengths, and lifetimes for the first 31 lowest energy levels in Cl-like nickel (Ni XII) [121]. We shall take into account all allowed $E1$ and forbidden $M1$, $E2$, and $M2$ transitions among these levels. These lines arise from three configurations $3s^23p^5$, $3s3p^6$ and $3s^23p^43d$. For these ions, theoretical complexity arises due to the near degeneracy characteristic and strong mixing of multiplets with the same total angular momentum J and parity π . Moreover, the atomic properties of such ions with seven valence electrons are quite sensitive to electron correlations and their interplay with relativistic effects. So, the elaborate size of wave function expansion along with the incorporation of correlation effects and effects of relativity on equal footing should be included in a computational model. This, indeed, is computationally very expensive and needs special care in terms of numerical convergence for the desired atomic properties.

The rest of the chapter is structured as follows. A short description of our computational procedures and correlation models are described in Sec. 5.1. In Sec. 5.2 the obtained data are discussed and compared with other *ab initio* and semi-empirical calculations and with experiments where available.

5.1 Computational details

We performed the calculations for two odd parity states which belong to the $3s^23p^5$ ground configuration with total angular momentum $J = 1/2$ and $J = 3/2$ and for the 29 even parity states from the $3s3p^6$ and $3s^23p^43d$ configurations with total angular momenta in the range $J = 1/2, \dots, 9/2$. We report two models of correlations calculations to investigate the importance of different non-dynamic and dynamic electron correlations effects [60]. In order to obtain the numerical convergence of the desired parameters, we systematically extended the configuration space using the method described in Sec. 2.5.

5.1.1 Model 1

In first model of calculations, the configurations $3s^23p^5$, $3s3p^6$ and $3s^23p^43d$ were taken as MR configurations for both even and odd parity states. In the lowest order approximation, the MCDHF calculations were performed simultaneously for even and odd parity states using the EOL scheme for the states in the MR set. All levels were given standard weights and a convergence for spectroscopic orbitals was achieved. In order to incorporate VV correlations only, we fixed the Ne like core ($1s^22s^22p^6$) i.e there is no virtual excitation from these orbitals. In subsequent calculations, we divided the states in six groups. One group for both of the odd states of the ground configuration and five separate groups of excited states with even parity corresponding to each total angular momentum $J = 1/2, \dots, 9/2$. Here in active set approach [cf. Sec. 2.5], separate MCDHF calculations were performed for each group of states for each layer. In first correlation layer we included SDTQ excitation within $3l$ sub-shells. This step is referred to as the $n = 3$ calculations. Similar calculations for $n = 4, \dots, 7$ are performed by including SD excitations from the MR configuration. For $n = 4$ the orbitals are *spdf* while for remaining higher layers we restrict ourselves to orbitals only up to g .

5.1.2 Model 2

In the second model of calculations, we took two separate MR sets for each even and odd parity symmetries. The configurations $3s^23p^5$, $3s3p^53d$, $3s^23p^33d^2$ and $3p^53d^2$ define MR set for the odd parity states and configurations $3s3p^6$, $3s^23p^43d$, $3s3p^43d^2$ and $3p^63d$ define MR set for the even parity states. In the lowest order approximation for this model, two separate MCDHF calculations for each parity were performed in EOL scheme for lowest 31 states by taking the weighted average of even and odd parity states. This lowest order approximation accounts for the nondynamic electron correlations that result from the close degeneracy of the orbitals [122]. For subsequent calculations, here again we divided the states into six groups in a similar way as in the first set of calculations. The rest of the approach for adding correlation layers is the same as in the first model of calculations but a single excitation from Ne-like core is also included in each correlation layer in order to incorporate CV correlations in addition to VV correlations. Here we name these VV+CV calculations as CV calculations. In this model of calculations the effects

of SDTQ excitations within $3l$ were negligible, therefore we restricted ourselves to single and double excitations to all correlation layers with a maximum azimuthal quantum number of h . In this model, the size of configuration space grows very rapidly so we restricted ourselves only with those CSFs which have non zero Hamiltonian matrix elements with CSFs of configurations in the MR sets. In this way there was an almost 20% decrease in the total number of CSFs, nevertheless, the number of CSFs in the final odd and even state expansions was approximately two million, as given in Table 5.1.

Each of the MCDHF calculation in both models was followed by a RCI calculation where we added Breit interaction, effects of vacuum polarization and self energy corrections. Then the transition parameter for the $E1, M1, E2$, and $M2$ transitions between the optimized states were calculated from the of transition matrix elements (2.35). For electric multipole transitions ($E1, E2$), calculations are performed for both gauges i.e. the length and the velocity forms. Presently, the quantity

$$dT = \frac{|A_l - A_v|}{\max(A_l, A_v)} \quad (5.1)$$

is used as an accuracy indicator of the transition rates for $E1$ and $E2$ transitions [103, 123].

Our procedure of a separate optimization for each group of levels in studying transition probabilities has the advantage that electron relaxation effects are automatically included to a large extent. The radial orbitals for each group of levels were not quite orthogonal with each other for which a transformation to a biorthonormal basis was applied as described in Sec. 2.7.

5.2 Results and discussion

In Table 5.1 we present the number of CSFs used in the atomic wave function expansion for different level groups for VV and CV correlations as a function of the size of the increasing active set labelled by the highest principle quantum number n of the orbitals in the set. This table manifests that the extent of computations increases significantly for non-dynamic correlations and CV correlations as compared

to VV correlations between each layer of the active set expansion.

Table 5.1: Number of CSFs used in the atomic state function for different level groups as a function of the size of the increasing active set labelled by the highest principle quantum number n of the of orbitals in the set.

In Table 5.2 we present the computed energies in Ni XII as a function of the increasing active set labelled by the n value of the orbitals in the set for both VV and CV correlations. Here the excitation energies are given relative to the $3s^23p^5$ $J = 3/2$ ground state and, as usual, we have assigned a level number in ascending order of the energy of each level, which is used in transition data tables to denote the individual transitions. Table 5.2 shows that the calculations are well converged with respect to increasing orbital set and our calculation set for CV correlations shows a more consistent convergence pattern for excitation energies with respect to an increasing size of the active space than VV correlations. It is obvious that the uncertainties cannot be further decreased by extending the orbital set to further layer of $n = 8$. Furthermore, we have found that the RCI calculations for each layer of calculations have reasonable effects on energy levels which is for layer $n = 7$ about $500 - 1500 \text{ cm}^{-1}$ for all levels. So, the Breit interaction and leading QED effects that are included in RCI computations are important along with MCDHF calculations for the exact prediction of energy levels.

In Table 5.3, we present a detail comparison of our theoretical energy values from the layer $n = 7$. For this purpose we have taken four datasets available in the literature. Firstly, we compare with the *ab initio* values of [124] because they have used a larger configuration space than previous *ab initio* computations [125, 126]. Secondly, theoretical values from the CHIANTI V.8 [127, 128] because these are considered the most appropriate data for astrophysical applications [11]. Thirdly, with the most recent semi-empirically predicted and tentative experimental data values of [54]. Fourthly, with the NIST database [88] which is considered as the most criti-

Table 5.2: Excitation energies in cm⁻¹ for NiXII as a function of the size of the increasing active set labelled by the highest principle quantum number n of the of orbitals in the set for valence-valence (VV) and core-valence (CV) correlations.

cally analysed database. Comparison with observed energies [54] and with the NIST values shows that the present *ab initio* values are not fully converged to experimental values. In order to achieve better accuracy relative to experimental values, we suggest more balanced and extended reference configuration sets as a starting point of the orbital expansion. This, however, results in very large expansions of wave functions which is computationally very expensive. Nevertheless, with the present set of calculations for CV correlations, results for the lowest 31 levels are better than obtained before in any *ab initio* investigation. A very good agreement with experiment is achieved to an accuracy better than 0.5% for low lying levels and 0.8% for higher lying levels whereas this accuracy is 1 – 2% for the MCDF calculations of Fritzsche *et al.* [124] and for SUPERSTRUCTURE calculations available at CHIANTI V.8 [127, 128]. In some more detail, there is no experimental connection in NIST database to the 5 levels with $J = 7/2$ and two levels with $J = 9/2$ for the $3s^23p^43d$ configuration with other levels. The present results of energies for these 7 levels with less than 0.45% error with new tentative experimental assignments [54] testify them. However, we suggest different level ordering than provided by semi-empirical formalism of [54]. We briefly discuss later the shift in level ordering and reasons for it. We also note that there is 2100 cm^{-1} difference between the latest experimental energy [54] and NIST database for the level no. 31 ($^2D_{3/2}$). The present value of $683\,070\text{ cm}^{-1}$ confirms the experimental energy [54] and we suggest a replacement in the NIST database with new experimental value.

Theoretically, level identification is always a difficult task because of the strong mixing of terms with same J and parity, whereas the mixing differs due to different set of configuration interaction and correlations. We provide LSJ mixing composition of terms for the 31 lowest states in Table 5.3. We found that our level ordering is same with SUPERSTRUCTURE calculations of Landi *et al.* [127] in the CHIANTI V.8 database for lowest order approximations and for the first correlation layer but they differ at two positions for our $n = 7$ correlation layer for the levels 16/17 ($^2F_{7/2}/^4P_{3/2}$) and 29/30 ($^2P_{1/2}/^2D_{5/2}$). Main reason for this could be the use of limited configuration interaction for their data set. Our level ordering as well as of Landi *et al.* differ from AUTOSTRUCTURE semi-empirical adjustments of Del Zanna and Badnell [54] at levels 8/9, 8 levels from level no. 11 to level no. 18 and then at levels 29/30. As many of the unknown levels are in this range, therefore, we have reason to believe that the term energy adjustments [55] in theoretical predictions of Del Zanna and Badnell [54] caused this level ordering difference. Additionally,

Table 5.3: Comparison of calculated and observed excitation energies in cm^{-1} for NiXII. Column 2 represents the LSJ mixing composition of terms for the 31 lowest states.

NIST: [88]

there seems to be a problem with the tentative experimental energy assignment to the term $^4P_{3/2}$, which is level no 17 in our predictions. Del Zanna and Badnell [54] assigned an experimental value of $504\,300\text{ cm}^{-1}$ to this level whereas present value of $512\,040\text{ cm}^{-1}$, [124] value of $514\,830\text{ cm}^{-1}$ and [127] value of $516\,378\text{ cm}^{-1}$ do not confirm this assignment. Moreover, there is no data available for the $^4P_{3/2}$ term in NIST database.

In the Table 5.4 we present our transition data in the region 146–316(Å) which is associated to $E1$ and $M2$ transitions from states of $3s3p^6$ and $3s^23p^43d$ to ground state $3s^23p^5$ levels. We have found that our calculations CV model are more stable in terms of accuracy between length and velocity form of $E1$ and $E2$ transitions. Here we present the data only in length form and used the velocity form in the estimation of the discrepancy of the two forms as given in Eq. 5.1. The lower values of dT do not represent an uncertainty estimate for each individual transition, but the average deviation within a given set of transitions, certainly provide inside into quality of the approximation. dT values of our results show a strong agreement between length and velocity gauge for all allowed strong transitions except for one weak intercombination transition from $^4D_{3/2} \rightarrow ^2P_{1/2}^o$.

Table 5.4: $E1$ and $M2$ transition energies cm^{-1} , transition wavelengths λ in Å, transition rates A (s^{-1}) and weighted oscillator strengths (gf) for the $3s^23p^5 - 3s3p^6$ and $3s^23p^5 - 3s^23p^43d$ lines of NiXII. Level number of lower and upper level refer to Table 5.3. gf and A (s^{-1}) values are displayed in length gauge only. Column 7 is uncertainty estimator dT among the $E1$ transition between length and velocity gauge which is given in Eq. (5.1). The notation $x \pm n$ represents $x \times 10^n$.

In Table 5.5, a brief comparison of our *ab initio* transition data are made with semi-empirical predictions for the *E1* transitions from the states of $3s3p^6$ and $3s^23p^43d$ to the ground states of $3s^23p^5$ configuration. Generally, our results of strong transitions agree very well with the semi-empirical calculations of Del Zanna and Badnell [54] with less than 5% for most of the transitions, however, they differ more than 20% for a few weak *E1* transitions. While our results for most of *E1* transitions are in the range of 15% with the CHIANTI V.8 [127, 128] database. Above all, our systematically enlarged wave functions in present case should be flexible enough to include the important correlations and provide clearly improved data for all intercombination and intra-combination transitions.

A brief comparison of our *M1* transition probabilities and transition wavelengths for a few intra-combination transitions is given in Table 5.6. This comparison shows that our *M1* transition rates are in very good agreement with semi-empirical adjusted values of CHIANTI V.8 [127, 128] and with Del Zanna and Badnell [54]. Moreover, our transition wavelengths for several *M1* transitions are better than the semi-empirical predictions of [54]. Overall, our predicted wavelengths for strong transitions deviate on the order of 0.8% while they excellently match for forbidden transition within the range of 1% deviation. From the comparison in Table 5.5 and 5.6 and by considering the agreement of our results from different gauges, we estimate the transition probabilities for all strong *E1* lines to be accurate within 5 – 10 per cent and for weak and forbidden transitions an accurate within 5 – 15 per cent.

We calculated the radiative lifetime τ of each excited level j from our calculated

Table 5.5: Comparison of $E1$ weighted oscillator strengths (gf), transition rates A (s^{-1}) with previous predictions. Notations are the same as in Table 5.4.

transition rates from the $n = 7$ computations using the following expression

$$\tau_j = \frac{1}{\sum_i A_{ji}}$$

and these are given in Table 5.7. These lifetimes of 30 excited states were calculated by including $E1$ and $E2$ transition rates in both length and velocity form as well as contributions from $M1$ and $M2$ transition rates. The average relative difference between length and velocity form is less than 4% for VV correlation whereas this difference is only 0.08% for the model including CV correlations. So our results with CV correlation are highly satisfactory in terms of computational consistency. There is a good agreement between theory and experiment for the first excited state $^2P_{1/2}^o$ which decays to ground state $^2P_{3/2}^o$ mainly by an $M1$ transition. The present value of 4.25 ms corroborates the semi-empirical value of 4.21 ms of the CHIANTI V.8 [127, 128] and benchmarks to the experimental value of 4.166 ± 0.060 ms which was performed at the heavy ion storage ring at Max Plank Institute for Nuclear Physics Heidelberg, Germany [96]. However, the 3.85 ms value of Del Zanna and Badnell [54] does not come in the range of experimental uncertainty. The next excited level is the $^2S_{1/2}$ of the $3s3p^6$ configuration which has two decay branches caused mainly by allowed $E1$ transition to the two ground state terms. The present value of 173 ps for this state is better than the 162 ps of CHIANTI V.8 [127, 128] and 138 ps of Del Zanna and Badnell [54] compared to the experimental value of (190 ± 10) ps [129], whereas other theories with value of 273 ps [125], 129.8 ps [126]

Table 5.7: Lifetimes (τ) in s for the low-lying levels of $3s^23p^5$, $3s3p^6$ and $3s^23p^43d$ are given in both length (τ_l) and velocity (τ_v) gauge including $E1$, $M1$, $E2$ and $M2$ transitions among lowest 31 levels. Notations are the same as in Table 5.4.

a : Experimental values form [96]

b : Experimental values form [129]

c : Experimental values form [51]

CHI: Theoretical values of CHIANTI V.8 [127, 128]

DZ: Theoretical values of [54]

as well as semi-empirical value of 238 ps [130] predicted a much scattered lifetime for this state.

As far as next 28 higher states arising from the $3s^23p^43d$ are concerned, only few experimental lifetimes are available and these are mainly based on beam foil spectroscopy [51]. As already discussed, the correlation effects for Ni XII like complex are rather large. So, 10% deviation from the theory is highly acceptable [129] for lifetimes. On the other hand lifetimes from the beam foil spectroscopy for many electron systems suffer from Doppler shift problems for the shorter lifetimes and from the cascade re-population for the longer lifetimes [11]. Nevertheless, the present lifetimes for the five levels have good agreement with the experiment. More specifically, the present lifetimes for level no. 19 ($^2D_{5/2}$) and 22 ($^2F_{5/2}$) are better than semi-empirical predictions. Although, the present lifetime for the level no. 13 ($^4F_{3/2}$) is better than semi-empirical values but it differs by a factor of two with the experiment. The CHIANTI V.8 [127, 128] and Del Zanna and Badnell [54] lifetime value for the level no. 17 ($^4P_{3/2}$) is better than the present value. For the level no. 11 ($^4F_{5/2}$) the lifetime of the CHIANTI V.8 [127, 128] is in very good agreement with experiment, however, the present value as well as value of Del Zanna and Badnell [54] matches with each other but differs by a factor of two with the experiment. Overall, from the comparison of length and velocity gauges and with the agreement with experiment and semi-empirical formalisms, we are confident that the present lifetime dataset will corroborate the future beam foil measurements and electron beam ion trap measurements with better quality than the semi-empirical formalism in a similar manner as the previous prediction for such ions [131–133].

6 Summary

In this thesis, we have presented high-precision calculations for rates and line strengths in various many-electron atomic systems in the view of high precision experiments. We started this thesis with a brief introduction in Chapter 1. In Chapter 2, we have demonstrated how the MCDHF wave functions for many-electron atomic systems are improved including the correlation, Breit, first order QED and finite nuclear mass corrections. Then we have shown how these wave functions are used to calculate the transition amplitudes necessary for the calculation of transition properties of different multi-pole expansions of the electromagnetic field.

In Chapter 3, we have presented highly accurate calculations for the line strengths of QED-sensitive forbidden transitions. We have extended the high precision evaluations previously performed for the middle Z B-like ions to higher Z as well as to different systems such as F-, Al-, and Cl-like ions. The obtained line strengths are further improved by rigorous calculations of the QED correction within an extended Furry picture approach. We used up-to-date accurate transition energies for the calculations of the $M1$ transition rates and reported lifetimes in the millisecond to picoseconds range. We believe that our accurate theoretical predictions provide the prerequisite for a test of QED by lifetime measurements at different frequencies and timescales. This will help to find a reason for the present discrepancies between theory and experiment for B-like Ar and Al-like Fe. Apart from testing atomic structure theory, such experiments in the future agreeing with the theoretical investigations will be very helpful for terrestrial and astrophysical plasma diagnostics.

In Chapter 4, we have presented high precision atomic calculations of the line strength of the $1s^22s2p\ ^1P_1 - 1s^22s^2\ ^1S_0$ spin allowed $E1$ transition in Be-like carbon. For the wave functions of the excited and ground state, we incorporated higher-order electron correlations, where the orbital relaxation and overlaps were taken into account by using separate and simultaneous set of relativistic orbitals in the active set. This has helped us to reliably estimate the uncertainty of the obtained line strength. Moreover, the finite nuclear mass correction to the line strength is calculated by correcting the energy, wave functions as well as the transition operator. The achieved relative uncertainty of the line strength amounts to

10^{-4} , which represents a reliable theoretical benchmark of $E1$ line strength in a view of upcoming high precision lifetime measurement of the $1s^22s2p\ ^1P_1$ state of Be-like carbon. Extensions of current studies to heavier Be-like ions allow us to improve the theoretical accuracy of transition rates. The given (numerical) uncertainty together with the high precision experiments will allow an alternative spectroscopic test than the energy alone and will provide further insight into the atomic structure of many-electrons atoms and ions.

Finally, in Chapter 5, We have presented calculations for the $E1, E2, M1$ and $M2$ transitions between $n = 3 \rightarrow 3$ states of Ni XII complex and critically compared it to other theories and experiment. We have achieved good numerical convergence for the desired parameters with our substantially extended computations comprising over two million CSFs. By incorporating all important relativistic and correlation contributions, we have achieved the same level of accuracy as semi-empirical calculations for observed transitions. We have justified the recently identified lines and suggested a level ordering for the first 31 levels based on the first principle. We have presented the pure *ab initio* lifetime values which are better than the values from the semi-empirical formalism as compared to the available experiments, therefore, we expect better accuracy than the semi-empirical tabulations for the upcoming experiments.

List of Figures

3.1	Feynman diagrams that represent the self-energy correction to the line strength. The wavy line indicates the photon propagator and the double line indicates the bound-electron wave functions and propagators in the effective potential being the sum of Coulomb and screening potentials. The single photon emission is depicted by the wavy line with arrow.	28
4.1	Scheme of a pump-probe experiment for atomic lifetime measurements of the $1s^2 2s 2p \ ^1P_1$ state in Be-like carbon. At time t_1 the XUV-pump pulse excites the $1s^2 2s^2 \ ^1S_0$ ground state of the Be-like carbon sample to the $1s^2 2s 2p \ ^1P_1$ excited state. The population $n(t)$ of the excited state 1P_1 decays then exponentially. A second and temporally delayed XUV-probe pulse probes the rest population of the excited state at time t_2 by ionizing Be-like carbon ion and maps out the exponential curve from which the decay rate is determined.	36
4.2	Schematic drawing of a XUV-pump XUV-probe experiment on Be-like carbon ions at CRYRING at GSI Darmstadt.	36
4.3	Comparison of the line strengths evaluated according to the Model 1 (TW) as a function of active set size of the orbitals with the results of Jönsson and Froese Fischer [32]. The green circles, red down triangles, and blue upper triangles display the present calculations in the length gauge S^l as well as in velocity gauges before S^v and after adjustment $S^v_{(\text{exp})}$ to the experimental transition energy ω_{exp} , respectively. The green hollow squares, red hollow diamonds, and blue hollow stars are corresponding values taken from Ref. [32].	41

4.4	Extent of different correlations effects to the transition energy with respect to the increasing n of the active set size defining the wave function expansion for the Model 2 calculations. The green circles represent VV correlations, magenta down triangles represent VV+CV, blue upper triangles represent VV+CV+CC, red-pentagons represent VV+CV+CC:SDTQ correlations. Please see the text for the details of different type of the correlations.	43
4.5	Convergence of transition energy with respect to the increasing n of the active set size defining the wave function expansion for the VV+CV+CC:SDTQ calculations of different correlation models. Please see the text for the details of the VV+CV+CC:SDTQ calculations.	45
4.6	Line strength for the for the VV+CV+CC:SDTQ calculations from the Model 2, Model 3 and Model MR plotted similarly as that of Fig. 4.3. In each sub-figure, the green circles are the line strength S^l in length form, red down triangles are <i>ab initio</i> S^v velocity from, blue upper triangles are $S^v_{(\text{exp})}$ velocity form adjusted the experimental transition energy ω_{exp} and black squares are $S^v_{(\text{exp-DC})}$ velocity from adjusted the experimental-Dirac-Coulomb transition energy $\omega_{\text{exp-DC}}$ (see text).	46
4.7	Line strength of the $1s^2 2s 2p \ ^1P_1 - 1s^2 2s^2 \ ^1S_0$ transition in Be-like carbon plotted against the present Models. Green squares represent to the length forms and blue circles to the velocity forms. The black solid line is the average of the both length and velocity forms. The gray shaded region is one standard deviation from the black line. . . .	47
4.8	A comparison of the present line strength of the $1s^2 2s 2p \ ^1P_1 - 1s^2 2s^2 \ ^1S_0$ transition in Be-like carbon with other theories and experiment. .	51

List of Tables

- 3.1 Correlation correction ΔS_{CI} to the $M1$ line strength of the transition between the fine-structure levels of the ground configuration for B-, F-, Al- and Cl-like Fe ions. The MCDHF and RCI methods are employed to evaluate these corrections considering Coulomb and Breit type interactions. They are presented as a function of the size of the increasing active set (AS) labeled by the highest principal quantum number n of the orbitals starting from the MR set. 27
- 3.2 Individual corrections to the $M1$ non-relativistic line strength $S_{\text{nr}} = 4/3$ for the $(2s^2 2p)^2 P_{1/2} - {}^2 P_{3/2}$ transition in B-like as well as for the $(2s^2 2p^5) {}^2 P_{3/2} - {}^2 P_{1/2}$ transitions in F-like Ar, Fe, Mo and W ions. The total line strength (S) is compared with other theories. The uncertainties involved in the calculation of line strengths are given within the parentheses. 30
- 3.3 Individual corrections to the $M1$ non-relativistic line strength $S_{\text{nr}} = 4/3$ for the $(3s^2 3p)^2 P_{1/2} - {}^2 P_{3/2}$ transition in Al-like as well as for the $(3s^2 3p^5) {}^2 P_{3/2} - {}^2 P_{1/2}$ transition in Cl-like Fe, Mo and W ions. The total line strength (S) is compared with other theories. The uncertainties involved in the calculation of line strengths are given within the parentheses. 31
- 3.4 Lifetimes τ_{pres} (in seconds) calculated for the $(2s^2 2p) {}^2 P_{3/2}$ level in B-like ions, the $(2s^2 2p^5) {}^2 P_{1/2}$ level in F-like ions, the $(3s^2 3p) {}^2 P_{3/2}$ level in Al-like ions and the $(3s^2 3p^5) {}^2 P_{1/2}$ level in Cl-like ions compared with experimental lifetimes (τ_{exp}). A^{M1} is the present transition rate (in s^{-1}) from the $M1$ channel and A^{E2} is the transition rate (in s^{-1}) from the $E2$ channel. The values of the transition energy used for the present lifetime calculations are given in cm^{-1} and corresponding transition wavelengths λ in Å. The uncertainties involved in the calculation of transition rate and lifetime arising due to uncertainties in the line strengths are given within the parentheses. The numbers given in the square brackets denote powers of 10. 33

4.1	Transition energies ω (cm^{-1}) and line strengths S (a.u.) for the $1s^2 2s 2p \ ^1P_1 - 1s^2 2s^2 \ ^1S_0$ transition in Be-like carbon as functions of the active set calculated within Model 1. The line strengths in the length gauge (S^l) are compared with those in the velocity gauge ab initially calculated (S^v) and after adjustment to the experimental energy ω_{exp} ($S^v_{(\text{exp})}$) and to the experimental-Dirac-Coulomb energy $\omega_{\text{exp-DC}}$ ($S^v_{(\text{exp-DC})}$). The experimental transition energy is taken from Ref. [88], while the experimental-Dirac-Coulomb energy is evaluated by subtracting the Breit, recoil, and QED corrections from the experimental transition energy.	42
4.2	ω is the Dirac-Coulomb transition energy (cm^{-1}). S^l and $S^v_{(\text{exp-DC})}$ are the Dirac-Coulomb line strengths in the length gauge and in the velocity gauge adjusted to $\omega_{\text{exp-DC}}$ energy (see text), in a.u.	48
4.3	The recoil corrections to the line strength originated from the energy and wave functions change, $\Delta S_{\text{rec,en+wf}}$, as well as due to the transition operator $\Delta S_{\text{rec,op}}$ calculated in the length and velocity gauges. The total gauge invariant recoil correction is presented in the last line. The values are in a.u.	49
4.4	Comparisons between different calculations and experiments for the line strength of the $1s^2 2s 2p \ ^1P_1 - 1s^2 2s^2 \ ^1S_0$ transition and the lifetime of the $1s^2 2s 2p \ ^1P_1$ excited state in Be-like carbon.	51
5.1	Number of CSFs used in the atomic state function for different level groups as a function of the size of the increasing active set labelled by the highest principle quantum number n of the of orbitals in the set.	56
5.2	Excitation energies in cm^{-1} for NiXII as a function of the size of the increasing active set labelled by the highest principle quantum number n of the of orbitals in the set for valence-valence (VV) and core-valence (CV) correlations.	57
5.3	Comparison of calculated and observed excitation energies in cm^{-1} for NiXII. Column 2 represents the LSJ mixing composition of terms for the 31 lowest states.	59

5.4	$E1$ and $M2$ transition energies cm^{-1} , transition wavelengths λ in \AA , transition rates A (s^{-1}) and weighted oscillator strengths (gf) for the $3s^23p^5 - 3s3p^6$ and $3s^23p^5 - 3s^23p^43d$ lines of NiXII. Level number of lower and upper level refer to Table 5.3. gf and A (s^{-1}) values are displayed in length gauge only. Column 7 is uncertainty estimator dT among the $E1$ transition between length and velocity gauge which is given in Eq. (5.1). The notation $x \pm n$ represents $x \times 10^n$	60
5.5	Comparison of $E1$ weighted oscillator strengths (gf), transition rates A (s^{-1}) with previous predictions. Notations are the same as in Table 5.4.	63
5.6	Selection of $M1$ transition rates A (s^{-1}), weighted oscillator strengths (gf) and wavelengths λ in \AA . Complete table for present $M1$ and $E2$ transition energies, transition rates, oscillator strengths and transition wavelengths is available online version of this article. Notations are the same as in Table 5.4.	64
5.7	Lifetimes (τ) in s for the low-lying levels of $3s^23p^5$, $3s3p^6$ and $3s^23p^43d$ are given in both length (τ_l) and velocity (τ_v) gauge including $E1$, $M1$, $E2$ and $M2$ transitions among lowest 31 levels. Notations are the same as in Table 5.4.	65

Publications

During this Ph.D. thesis, the author has contributed to the following publications:

- Ab initio calculations of energy levels, transition rates and lifetimes in Ni xii

Ehrenwörtliche Erklärung

Ich erkläre hiermit ehrenwörtlich, dass ich die vorliegende Arbeit selbstständig, ohne unzulässige Hilfe Dritter und ohne Benutzung anderer als der angegebenen Hilfsmittel und Literatur angefertigt habe. Die aus anderen Quellen direkt oder indirekt übernommenen Daten und Konzepte sind unter Angabe der Quelle gekennzeichnet.

Bei der Auswahl und Auswertung folgenden Materials haben mir die nachstehend aufgeführten Personen in der jeweils beschriebenen Weise unentgeltlich geholfen: Prof. Dr. Stephan Fritzsche und Dr. Andrey V. Volotka.

Weitere Personen waren an der inhaltlich-materiellen Erstellung der vorliegenden Arbeit nicht beteiligt. Insbesondere habe ich hierfür nicht die entgeltliche Hilfe von Vermittlungs- bzw. Beratungsdiensten (Promotionsberater oder andere Personen) in Anspruch genommen. Niemand hat von mir unmittelbar oder mittelbar geldwerte Leistungen für Arbeiten erhalten, die im Zusammenhang mit dem Inhalt der vorgelegten Dissertation stehen.

Die Arbeit wurde bisher weder im In- noch im Ausland in gleicher oder ähnlicher Form einer anderen Prüfungsbehörde vorgelegt.

Die geltende Promotionsordnung der Physikalisch-Astronomischen Fakultät ist mir bekannt.

Ich versichere ehrenwörtlich, dass ich nach bestem Wissen die reine Wahrheit gesagt und nichts verschwiegen habe.

Curriculum Vitae

Personal Information

Name	Moazzam Bilal
Gender	Male
Nationality	Pakistani
Date of birth	28.08.1981
Place of birth	Gujranwala, Pakistan
Marital status	Married

School education

1987 – 1992	Govt. Primary School Dahaunkal, Gujranwala, Pakistan
1992 – 1995	Punjab Model High School Wazirabad, Pakistan
1995 – 1997	Govt. Model High School Kasur, Pakistan
1997 – 2000	Govt. FC College Lahore, Pakistan

University education

2000 – 2003	Bachelor in Physics, Government Islamia College Civil Lines, University of the Punjab, Lahore, Pakistan
2003 – 2006	Master in Physics, Department of Physics, University of the Punjab, Lahore, Pakistan
2007 – 2008	M.Phil in Physics, Pakistan Institute of Engineering and Applied Sciences, Islamabad, Pakistan

Employment

2009 – 2015	Research fellow in Department of Physics and Applied Mathematics, Pakistan Institute of Engineering and Applied Sciences, Islamabad, Pakistan
2016 – 2019	PhD scholar in Helmholtz Institute Jena, Friedrich Schiller University Jena, Germany under DAAD / HEC-Pakistan scholarship program
